A WEEKLY

ILLUSTRATED JOURNAL OF SCIENCE

VOLUME LVII

NOVEMBER 1897 to APRIL 1898

> "To the solid ground
> Of Nature trusts the mind which builds for aye."—WORDSWORTH

London
MACMILLAN AND CO., LIMITED
NEW YORK THE MACMILLAN COMPANY

Richard Clay and Sons, Limited,
london and bungay.

INDEX

Abegg (R.), Dielectric Constants at Low Temperatures, 70; Nature of Coloration of Salts by Kathode Rays, 92

Abercromby (Hon. Ralph), Obituary Notice of, R. H. Scott, F.R.S., 55

Aberration, Constant of, Prof. C. L. Doolittle, 472

Abney (Captain), Physical Aspects of Reversal of Photographic Image, 158

Abnormal Colours of Flowers, Hector Colwell, 129

Abridged Long Division, Rev. C. L. Dodgson, 269; Robert W. D. Christie, 390

Absorption, Dew and, T. Wilson, 436

Accidents, Mine, in 1897, 277

Acetylene: L'Eclairage à l'Acétylène, G. Pellissier, 219; Calcium Carbide and, Henry Fowler, 523

Ackermann (Mr.), New Physical Experiments, 23

Acoustics: Lessons in Elementary Practical Physics, vol. iii., part 1. Practical Acoustics, C. L. Barnes, 218; Colour-Hearing, Dr. W. S. Colman, 229; the Microphonograph, Dr. Louis Ollivier, 255; Means of Producing Elliptic Sound-Vibrations in Air, M. Crémieu, 440; Sound-Propagation through Non-Homogeneous Medium, N. Kasterin, 528

Actinograph, a New, Dr. Hurter and V. C. Driffield, 471

Actinometry in Balloons, J. Violle, 47

Adie (R. H.), Agricultural Chemistry, 196

Adulteration; Detection of Sawdust in Flour, G. A. Le Roy, 576

Aerial Navigation, Navigazione Aerea, Guglielmo N. Da Pra, 560

Aeronautics: Herr Andrée's Expedition, Jonas Stadling, 14; Andrée and his Balloon, Henri Lachambre and Alexis Machuron, Dr. H. Robert Mill, 609; Apparatus for Verifying Barometric Measurement of Balloon Altitudes, L. Cailletet, 23; Photographic Method of Measuring Height of Balloon, L. Cailletet, 282; Actinometry in Balloons, J. Violle, 47; Artificial Wings in Imitation of Flying-Fox, Major R. F. Moore, 59; Les Ballons-Sondes, W. de Fonvielle, 76; the International Balloon Conference, W. de Fonvielle, 565; Electric Balloon Signalling applied to Arctic Exploration, E. S. Bruce, 85; Artificial Flight, Prof. G. H. Bryan, F.R.S., 135; a Railroad Flying Machine, Profs. Langley and Watkins, 156; Experiments in Gliding Flight, Octave Chanute, 255

Afialo (F. G.), a Sketch of the Natural History (Vertebrates) of the British Isles, 533

Africa: Ten Years' Rainfall of Cape Colony, Dr. Buchan, 34; the Dry Crushing and Direct Cyaniding of Rand Ore, 135; Daily Range of Meteorological Elements at Cairo, Dr. J. Hann, 165; Death of Dr. Eugen Zintgraff, 228; Obituary Notice of, 254; Manners and Habits of Natives of East Africa Protectorate, Sir A. Hardinge, 372; Rinderpest and Serotherapy in South Africa, 398; the Rainfall of South Africa, 114; British Central Africa, Sir Harry H. Johnston, 174; Stridulation in some African Spiders, R. I. Pocock, 356; Giraffe from the Niger Territories, W. Hume McCorquodale, 389; the Navigability of the Niger, Lieut. de Chevigne, 442; Zoological Evidence of Connection of Lake Tanganyika with the Sea, J. E. S. Moore, 476; Iceland Spar from Kilwa Island, W. R. Dunstan, 491; Discovery of Tomb of Amenophis II., G. M. Loret, 566

Agamennone (Dr. G.), New Electric Seismoscope, 59

Agassiz (A.), Coral Reefs of Fiji Group, 405

Agriculture: the Fertility of the Land, Isaac P. Roberts, 75; Effect of Temperatures on Hibernation of Injurious Insects, Dr. L. O. Howard, 85; Light and Beetroot Sugar Production, F. Strohmer, 159; Potato Disease, G. W. Bulman, 198; Oat, Wheat, and Rye Straw, M. Balland, 239; the Foundations of Scientific Agriculture, Samuel Cooke, 243; West Indian Resources, D. Morris, 464; Damage to Soil by Salt-water Flood, T. S. Dymond, 490; the Gipsy Moth in Massachusetts, L. O. Howard, 491; Report of Observations of Injurious Insects and Common Farm Pests, Eleanor A. Ormerod, 558; the West Australian Settler's Guide and Farmer's Handbook, 560; Death and Obituary Notice of Prof. Aimé Girard, 587; Tobacco Soils of United States, M. Whitney, 615; Absorption of Organic Materials by Roots, Jules Laurent, 143; Agricultural Chemistry, R. H. Adie, 196; Influence of Bismuth Subnitrate on "Hardening" of Cider, MM. Leon Dufour and Daniel, 239; Agriculture in some of its Relations with Chemistry, F. H. Storer, 292; Oxidation of Ammonia Compound by Soil-Ferments, E. Demoussy, 310; Caron's New Bacteriological Grain Manure, "Alinit," 418

Air and Water, Electric Movements on, with Theoretical Inferences, Lord Armstrong, F.R.S., 31

Air, the Exploration of the, by Means of Kites, A. Lawrence Rotch, 53

Air, Food, and Exercises: an Essay on the Predisposing Causes of Disease, Dr. A. Rabagliate, 99

Alaska, J. G. Brady, 103

Albino Lark, an, 228

Alcock (Sir Rutherford), Death of, 12

Alcohol in Relation to Microbial Diseases, Dr. Deléarde, 355

Alcoholic Fermentation, Yeast and, Prof. J. Reynolds Green, F.R.S., 591

Alembic Club Reprints, No. 13; the Early History of Chlorine, No. 14; Researches on Molecular Asymmetry, 534

Algebra: Chambers's Algebra for Schools, William Thompson, 388

"Alinit," a New Bacteriological Grain Manure, Herr Caron, 418

Allen (A. U.), Death and Obituary Notice of, 612

Allen (Francis H.), Nature's Diary, 364

Allen (Dr. Harrison), Death of, 102

Alloys: Microscopic Study of Alloys, 11

America: American Association for the Advancement of Science Meeting at Detroit, Experimental Morphology, Prof. G. F. Atkinson, 41; Geologists in Canada, 62; American Journal of Science, 70, 189, 333, 404, 500; Volcanoes of North America, Israel C. Russell, 73; Life Histories of American Insects, C. M. Weed, 99; Bulletin of American Mathematical Society, 164, 308, 357, 476, 598; Modification of the Great Lakes by Earth Movement, Prof. G. K. Gilbert, 211; the Gallinaceous Game Birds of North America, D. G. Elliot, 219; Stanford's Compendium of Geography and Travel, North America, S. E. Dawson, vol. i., Canada and Newfoundland, Dr. Hugh Robert Mill, 223; American Journal of Mathematics, 261; American Society of Naturalists, Sixteenth Annual Meeting, 281; Crater Lake, Oregon, 375; Further Explorations in American Mounds, 400; Does a Phosphorescent South American Liana exist? Prof. Italo Giglioli, 412; the Lake Superior Iron Ore Region, Bennett H. Brough, 473; Twenty-first Annual Report of the Department of Geology and Natural Resources, Indiana, W. S. Blatchley, 484; Glaciation of North America, Dr. J. W. Spencer, 571; R. Chalmers, 571; J. B. Tyrrell, 572; Dr. G. W. Dawson, 572; Prof. C. H. Hitchcock, 572; Prof. A. P. Coleman, 572;

Bayley Willis, 573; Prof. H. L. Fairchild, 573; F. B. Taylor, 573; John Cabot's Landing-place in America, Dr. S. E. Dawson, 616
Amsterdam Royal Academy of Sciences, 95, 191, 263, 311, 455, 527
Anatomy: Death of Doctor Harrison Allen, 102; Death of Dr. Hugh Calderwood, 253; Journal of Anatomy and Physiology, 318; Anatomy of *Macropus rufus*, Prof. B. Windle and F. G. Parsons, 319; Lehrbuch der Vergleichenden Mikroskopischen Anatomie der Wirbelthiere, Dr. Med. Alb. Oppel, 581
Anceaux (Émile), Planetary Relations, 352
Ancient Geography, a History of, H. F. Tozer, 482
Ancient Stone Implements, Weapons, and Ornaments of Great Britain, the, Sir John Evans, K.C.B., 290
Ancient World, Natural History of the, 146
Andeer (J. J.), Leucocyte-generating Apparatus in Peritoneum, 191
Anderson (Dr.), New Variable Stars, 179
André (G.), Combinations of Pyridine and Trimethylamine with Formic and Acetic Acids, 600
Andrée Expedition, the, Jonas Stadling, 14
Andrée and his Balloon, Henri Lachambre and Alexis Machuron, Dr. H. Robert Mill, 609
Andrews (Gwendolen Foulke), the Living Substance as such, and as Organism, 362
Andrews (Thomas), Microscopic Observations on Fatigue-deterioration in Steel Rails, 58
Anemometry, 103; a Method of Measuring Wind Pressure, Prof. Francis E. Nipher, 449
Animal Electricity, Lectures on Physiology, First Series, on, A. D. Waller, F.R.S., 50
Animals, All About, for Old and Young, 172
Animals, Tame, Wild Traits in, Dr. Louis Robinson. 150
Animals, Instinct and Intelligence in, Prof. C. Lloyd Morgan, 326
Animals and Plants, Marine, the Preparation of, as Transparent Lantern Slides, Dr. H. C. Sorby, F.R.S., 520
Annable (H.), Benzoylphenylsemicarbazide, 93
Annelids, Origin of Setigerous Bulbs and Nephridia in, Aug. Michel, 263
Annuaire pour l'An 1898, publié par le Bureau des Longitudes, 244
Annuaire de l'Oberservatoire Municipal de Montsouris pour l'Année 1898, 244
Antarctic Expedition, Scientific Advantages of an, Dr. John Murray, F.R.S., 420; the Duke of Argyll, F.R S., 423; Sir Joseph Hooker, F.R.S., 423; Dr. Nansen, 424; Prof. Dr. Neumayer, 424; Sir Clements Markham, F.R.S., 424; Dr. Alexander Buchan, 425; Sir Archibald Geikie, F.R.S., 426; Dr. P. L. Sclater, F.R.S., 427; Prof. D'Arcy W. Thompson, 427
Antarctic Research, Dr. Hugh Robert Mill, 413
Antares, Occultation of, 442
Anthropology: Relation between Individual and Racial Variability, Edwin Tenney Brewster, 16; Early Man in Scotland, Sir Wm. Turner, F.R.S., 234, 256; Arii e Italici, Prof. G. Sergi, 268; the Cambridge Expedition to Torres Straits and Borneo. Prof. Alfred C. Haddon, 276; Characteristics of European Races, J. Deniker, 351; Manners and Habits of Natives of East Africa Protectorate, Sir A. Hardinge, 372; Man in Relation to the Glacial Period, Dr. H. Hicks, F.R.S., 402; Anthropological Institute, 430, 526; Native Life in Central Australia, Prof. W. B. Spencer, 496; Aborigines of Formosa, Albrecht Wirth, 518; the Guayaki of Paraguay, Dr. Ehrenreich, 551; the Moplahs of Malabar, Dr. Emil Schmidt, 551; Globus, 551; Recherches sur les Origines de l'Egypte, J. de Morgan, 578
Anticyclonic Systems, Major H. E. Rawson, 623
Antiquity, the Metals used by the Great Nations of, Dr. J. H. Gladstone, F.R.S., 594
Antoniadi (M.), the Doubling of the Canals on Mars, 568
Ants and Aphides, J. G. Goudie, 517
Appleyard (Rollo), Failure of German Silver and Platinoid Wires, 116; the Material of Resistance Coil Wire in Tropical Climates, 418
Applied Mechanics, Prof. John Perry, F.R.S., Prof. J. A. Ewing, F.R.S., 313
Applied Mechanics, a Text-book on, Andrew Jamieson, 483
April Lyrids, the, 568
η Aquilæ, Spectrum Researches of, Prof. A. Belopolsky, 353
Arachnidæ: Stridulation in some African Spiders, R. I. Pocock, 356
Archæology: Archæological Studies among the Ancient Cities of Mexico, W. H. Holmes, 6; the Reliquary and Illustrated Archæologist, 29; Congress of Societies, 156; Babylonian Land Surveying, Prof. Hammer, 281; Palæolithic Man, F. T. Newton, F.R.S., 354; Further Explorations in American Mounds, 400; the Temple-Pyramid of Tepotzlan, Dr. E. Seler, 551; Discovery of Tomb of Amenophis II. by M. Loret, 566; Prehistoric Ruins of Honduras and Yucatan, Alfred P. Maudslay, 568; Recherches sur les origines de l'Egypte, J. de Morgan, 845
Archibald (E. H.), Conductivity of Aqueous Solutions of Potassium and Sodium Sulphates, 398
Archimedes, the Works of, Dr. T. L. Heath, 409
Architecture: Modern Architecture, H. H. Statham, 602
Arcimus (Prof. Augusto), Dust Fog in the Canaries, 582
Arctica: the Andrée Expedition, Jonas Stadling, 14; the Jackson-Harmsworth Arctic Expedition, 40; the Land Fauna of Spitsbergen, D. J. Scourfield, 60; David Bryce, 60; Electric Balloon Signalling applied to Arctic Exploration, E. S. Bruce, 85; the Arctic Work of Mr. R. E. Peary, 132; a Proposed Swedish Expedition to the Arctic Regions, Dr. A. G. Nathorst, 163; the Lava Sheets of Franz Josef Land, Messrs. Newton and Teall, 324; Mammals of Franz Josef Land, W. S. Bruce, 575; Birds of Franz Josef Land, W. E. Clark, 575
Arequipa Observatory, the, 249
Argon, the Spectra of, Dr. Rydberg, 157
Argyll (the Duke of, F.R.S.), Scientific Advantages of an Antarctic Expedition, 423
Arii e Italici, Prof. G. Sergi, 268
Aristotle on Youth and Old Age, Life and Death, and Respiration, Dr. W. Ogle, 146
Arithmetic: Abridged Long Division, Rev. C. L. Dodgson, 269; Robert W. D. Christie, 390; the Miner's Arithmetic and Mensuration, Henry Davies, 462; an Arithmetic for Schools, S. L. Loney, 560
Armenia, Notes on some Volcanic Phenomena in, T. McKenny Hughes, 392
Armitage (Miss E.), Early Spring Flowers, 365
Armitage (F. P.), Atomic Weight of Boron, 383
Armstrong (Lord, F.R.S.), Electric Movement on Air and Water with Theoretical Inferences, 31
Arnold-Bemrose (H. H.), Quartz-rock in Carboniferous Limestone of Derbyshire, 406
Arnott (R. F.), Gold in Silver, 205
Arons (L.), Temperature of Mercury Arc Lamp Electrodes, 238
Arrhenius's Views on Causes of Climate Variations Criticised, L. de Marchi, 614
Artillery Chronograph, a New, 368
Artist's Pigment, Oat Smut as an, David Paterson, 364; Prof. H. Marshall Ward, F.R.S., 389; Kumagusu Minakata, 437
Aryo-Semitic School of Mythology, R. Brown, jun., 530
Asbarg, Colouring Matters of Indian Dye-stuff, A. G. Perkin and J. A. Pilgrim, 478
Aschkinass (E.), Deflection of Kathode Rays, 238
Ashford (C. E.), the Use of Compressed Coal Gas, 485
Ashworth (J. R.), Method of Making Magnets Independent of Changes of Temperature, 261
Assyria: the Metals used by the Great Nations of Antiquity, Dr. J. H. Gladstone, F.R.S., 596
Aston (E.), Influence of Temperature on Rotatory Power of Liquids, 120
Astronomy: the November Meteors (Leonids), 7, 61, 88; W. F. Denning, 7, 30, 36, 82; Spectrum of a Meteor, Prof. E. C. Pickering, 101; Some Systems of Meteors, Prof. Th. Bredikine, 105; Geminids, 136; a Remarkable Meteor, Henry Cecil, 204; Remarkable Meteoric Display, 228; a Bright Meteor, Susanna Lehmann, 271; the Height of Meteors, W. F. Denning, 540; the April Lyrids, 568; the Meudon Observatory, 568; Our Astronomical Column, 16, 35, 61, 88, 105, 136, 159, 179, 207, 230, 256, 284, 303, 325, 352, 374, 399, 419, 442, 472, 491, 519, 546, 568, 591, 617; the Photography of Faint Moving Celestial Objects, Prof. Barnard, 16; Photography of Unseen Moving Celestial Objects, Prof. Barnard, 230; Sunspots and the Weather, A. Macdowall, 16; Theory of Sunspots, Prof. J. Joly, F.R.S., 239; Level of

Sunspots, 284; the Director of the Lick Observatory, 16; Comet Perrine (October 16), 16, 88, 492; Herr J. Möller, 16, 61, 105; Dr. F. Ristenpart, 519; Prof. H. Kreutz, 568, 591, 617; Winnecke's Periodic Comet, 180, 284, 472; Prof. Perrine, 230; Winnecke's Comet = *a* 1898, 325, 352; Theory of Periodic Comets, M. Callandreau, 303; the Comet of 1892 II, Dr. L. Steiner, 325; Velocity of Solar System, Prof. J. C. Kapteyn, 191; the Total Eclipse of the Sun (1898), 35, 105, 294, 325, 365; Sir Norman Lockyer, K.C.B., F.R.S., 342; Arrival of Eclipse Parties at Bombay, 230; the Total Solar Eclipse of 1900, 159; Eclipse Negatives, 419; the Binary β 395 = 82 Ceti, Dr. T. J. J. See, 36; Telescopic Seeing, 36; Die Meteoriten in Sammlungen und ihre Literatur, Dr. E. A. Wülfing, 53; Spectrum Analysis of Meteorites, W. N. Hartley and Hugh Ramage, 546; Jupiter's Third and Fourth Satellites, Prof. Barnard, 61; the Present Appearance of Jupiter, W. F. Denning, 586; the Variable Star β Lyræ, Herr Pannekoek, 61; New Investigations of β Lyræ, Prof. A. Belopolsky, 207; the Variable Star *o* Ceti (Mira), 105, 136; the Variability of Mira Ceti, David Flanery, 245; Variables S Cephei and T Ursæ Majoris, C. E. Peek, 105; New Variable Stars, 179, 472; Dr. Anderson, 179; *Variables in Star Clusters*, 400; *the Variables S. Cassiopeiæ and S. Ursæ Majoris*, Mr. Peck, 492; Two New Variable Stars of Short Period, Herren G. Müller and P. Kempf, 519; Variables and their Comparison Stars, Prof. E. C. Pickering, 519; Obituary Notice of Prof Ernst Schering, 85; Theory of the Motion of the Moon, Ernest W. Brown, 88; Corrected Position of the Moon, M. Lágrula, 159; Partial Eclipse of the Moon, 207; Current Astronomical Articles, 88; Systematic Observations of Occultations, Herr H. Batterman, 105; Occultation of Ceres, 400; Occultation of Antares, 442; Astronomical Constants at the Paris Conference, Dr. Fr. Porro, 127; Death of Prof. F. A. T. Winnecke, 133; Obituary Notice of, 155; the Companion of Sirius, Dr. See, 136; a Liberal Gift to Astronomy by Miss Alice Bache Gould, 137; Employment of Method of Least Squares to detect Systematic Errors, J. Mascart, 143; the Orientation of Greek Temples, F. C. Penrose, F.R.S., 151; Opposition of Two Minor Planets, 159; Minor Planets in 1897, 256; a New Form of Mirror for a Reflecting Telescope, 160; Memorials of William Cranch Bond and George Phillips Bond, Edward S. Holden, Dr. W. J. S. Lockyer, 171; New Double Stars, R. T. A. Innes, 179; Variations in the Spectrum of Nebula in Orion, 180; Nebulæ near Castor, Prof. Barnard, 326; Telescope for Nebulæ, J. Janssen, 359; New *Photographs of Nebulæ, M. A. Rabourdin, 374; the Photography* of Nebulæ, Prof. R. A. Gregory, 443; Large Refracting and Reflecting Telescopes, W. J. S. Lockyer, 200; Astronomical Occurrences in January 1898, 207; Astronomical Occurrences in February 1898, 303; Astronomical Occurrences in March 1898, 399; Astronomical Occurrences in April 1898, 519; Astronomical Occurrences in May 1898, 617; Nautical Almanac Corrigenda, 1898, 207; Nautical Almanac 1901, 442; Occultation of the Pleiades, 207; the Atmospheres of Planets, Dr. Johnston Stoney, 207; Planetary Relations, Emile Anceaux, 352; Atlas der Himmelskunde auf Grundlage der Ergebnisse der coelestischen Photographie, A. v Schweiger-Lerchenfeld, 220; Death of Arthur Kammerman, 228; Obituary Notice of, 256; Mont Blanc Observatory, M. J. Janssen, 230; Astronomical Annuals, 230; Annuaire pour l'An 1898, publié par le Bureau des Longitudes, 244; the Arequipa Observatory, 249; Companion to Vega, Prof. Barnard, 256; Harvard College Report, Prof. Pickering, 256; Appointment of Prof. G. M. Searle to the Vatican Observatory, 256; the Concise Knowledge of Astronomy, Agnes M. Clerke, A. Fowler, and J. Ellard Gore, 266; Death of Dr. Eduard Lindemann, 280; Obitury Notice of, 299; Death of Dr. Oscar Stumpe, 280; Obituary Notice of, 299; a New Spectroscopic Binary, 284; a Variable Bright Hydrogen Line, Miss A. J. Cannon, 284; Astronomical Constants, 284; *Longitude of Madras*, 284; Photographic Magnitudes, Prof. Pickering, 303; the Constitution and Function of Gases, Severinus J. Corrigan, 316; Large and Small Proper Motions, Prof. Kapteyn, 325; Rowland's Tables, 326; Obituary Notice of Dr. Karl Necker, 326; U Pegasi and Short Period Variables, O. C. Wendell, 352; Variable Star, U Pegasi, 442; Astronomical Annual for 1898, 353; Spectrum Researches of η-Aquilæ, Prof. A. Belopolsky, 353; Carbon in the Chromosphere, Prof. Hale, 374; Parallax of Sirius, Dr. Gill, 374; a Probable New Star, Rev. T. E. Espin, 374; Address to the Royal Astronomical Society, Sir Robert Ball, F.R.S.; and Presentation of Gold Medal to W. F. Denning, 376; the Observer's Atlas of the Heavens, William Peck, 388; Periodic Orbits, Prof. G. H. Darwin, 394; Another Lunar Hoax, 399; a Remarkable Object, Rev. T. E. Espin, 400; a Large Reflecting Telescope, Rev. John Peate, 400; Parallaxes of Stars, Dr. Gill, 400; Astronomical Photography, Dr. Isaac Roberts, 417; Cinematograph in Astronomy, M. Camille Flammarion, 419; a Probable New Star, 419; Electrolytic Reflectors, Sherard Cowper-Coles, 419; Constant of Aberration, Prof. C. L. Doolittle, 472; Astronomical Serials, 472; Magnitudes of 1081 Southern Stars, Stanley Williams, 491; Occultations Photographically observed, Prof. E. C. Pickering, 492; *Astronomy in Australasia*, P. Baracchi, 493; Concave Gratings for Stellar Photography, 520; a Catalogue of 636 Stars, Herr W. Luther, 520; Annals of the Cape Observatory, 513; Death and Obituary Notice of Prof. W. A. Rogers, 516; Favourable Apparition of Mercury, 519; Mr. Wood's Method of Illustrating Planetary Orbits, Prof. Louis W. Austin, 536; Stellar Parallaxes, Dr. Bruno Peter, 546; *the Doubling of the Canals on Mars, M. Antoniadi*, 568; the Aurora Spectrum, Prof. E. C Pickering, 591; the Movement of Solar Faculæ, Dr. W. Stratonoff, 591; Das Weltgebäude. —Eine Gemeinverstandliche Himmels-kunde, Dr. M. Wilhelm Meyer, 604; Double and Multiple Southern Stars, Dr. T. J. J. See, 617; the Manora Observatory, Herr Leo Brenner, 617; Harvard College Observatory, Prof. Pickering, 617
Astruc (A.), Neutralisation of Glycerophosphoric Acid, 191
Asymmetry, Researches on Molecular, Alembic Club Reprints, 534
Atkinson (E. Cuthbert), the Solution of Quadratic Equations, 463
Atkinson (Prof. G. F.), Experimental Morphology, 41
Atlantic, North, Severe December Weather in, 282.
Atlas der Himmelskunde auf Grundlage der Ergebnisse der cœlestischen Photographie, A. v. Schweiger-Lerchenfeld, 220
Atlas of the Heavens, the Observer's, William Peck, 388
Atmospheres of Planets, the, Dr. Johnston Stoney, 207
Atmospheric Pressure, Undulations in Lakes and Inland Seas due to Wind and, W. H. Wheeler, 321
Atomic Weight of the Metals Contained, the Connection between the Characters of Isomorphous Salts and the, A. E. Tutton, 36
Atomic Weights of Nickel and Cobalt, the, 374
Audubon and his Journals, Maria R. Audubon, 386
Augury from Combat of Shell-fish, on, Kumagusu Minakata, 342
Aurora of March 15, the, A. Geo. Smith, 511
Aurora Spectrum, the, Prof. E. C. Pickering, 591
Austin (Prof. Louis W.), Mr. Wood's Method of Illustrating Planetary Orbits, 536
Australasian Association, the, 493; Presidential Address, Prof. A. Liversidge, F.R.S., 493; Astronomy and Terrestrial Physics, P. Baracchi, 493; Measurements of Cloud Heights and Velocity, P. Baracchi, 493; the Sources of Periodic Waves, H. C. Russell, F.R.S., 493; Seismological Work in New Zealand, George Hogben, 494; Molecular Mechanism of Electrolyte, W. M. Hamlet, 494; Red Rain Dust, Thomas Steel, 494; Early Life on Earth, Prof. F. W. Hutton, F.R.S., 494; the Funafuti Coral-boring Expedition, Prof. David, 494; Glacial Traces in Inman Valley, South Australia, Prof. T. W. E. David and Walter Howchin, 495; Glacial Boulders at Yellow Cliff, Central Australia, Prof. W. B. Spencer and P. M. Byrne, 495; Evidence of Glacial Action in Bacchus Marsh District, C. C. Brittlebank, G. Sweet and Prof. David, 495; Geology of West Australia, 495; E. L. Pittman, 495; Artesian Water in New South Wales, Rev. J. M. Curran, 495; Glaciation in Australia, Rev. J. M. Curran, 495; Submarine Geography, Sir James Hector, F.R.S., 495; Antarctica, Sir James Hector, F.R.S., 496; the Exploration of Central Australia, W. H. Tietkins, 496; Origin of Australasian Aborigines, A. W. Howitt, 496; Native Life in Central Australia, Prof. W. B. Spencer, 496.
Australia: Report of Australian Museum, Sydney, 15; Remarkable Termite Mounds of Australia, W. Saville-Kent, 81;

Geology of Western Australia, Dr. O. Holst, 86; My Fourth Tour in Western Australia, Albert F. Calvert, 126; the West Australian Settler's Guide and Farmer's Hand-book, 560

Babcock (S. M.), Cheese-ripening, 373
Babington (Charles Cardale), Memorials, Journal and Botanical Correspondence of, 314

REVIEWS AND OUR BOOKSHELF:
Researches on Mimicry on the Basis of a Natural Classification of the Papilionidæ, Dr. Erich Haase, 1, 25
A Memoir of William Pengelly, F.R.S., 4
Archæological Studies among the Ancient Cities of Mexico, W. H. Holmes, 6
Manuale del Chimico e dell' Industriale, Prof. Dr. L. Gabba, 7
La Fabbricazione dell' Acido Solforico, dell' Acido Nitrico, del Solfato Sodico, dell' Acido Muriatico, Dr. V. Vender, 7
Leghe Metalliche ed Amalgame, I. Ghersi, 7
Lectures on Quaternions, S. Kimura, 7
Lehrbuch der Erdkunde für höhere Schulen, Dr. Willi Ule, 7
The Great Meteoric Shower of November, W. F. Denning, 7
Lectures on the Action of Medicines, T. Lauder Brunton, F.R.S., 26
Organic Chemical Manipulation, J. T. Hewitt, 28
Nights with an Old Gunner, and other Studies of Wild Life, C. J. Cornish, 29
Untersuchungen über den Bau der Cyanophyceen und Bakterien, A. Fischer, 29
Electricity and Magnetism for Beginners, F. W. Sanderson, 29
Organic Chemistry for the Laboratory, Prof. W. A. Noyes, Dr. A. Harden, 29
The Reliquary and Illustrated Archæologist, 29
The Commercial Uses of Coal Gas, Thomas Fletcher, 29
The Theory of Electricity and Magnetism, being Lectures on Mathematical Physics, A. G. Webster, 49
Lectures on Physiology, A. D. Waller, F.R.S., 50
Memories of the Months; being pages from the Note-book of a Field Naturalist and Antiquary, to wit, Sir Herbert Maxwell, Bart, 51
Notes on Micro-organisms Pathogenic to Man, Surgeon-Captain B. H. S. Leumann, 52
The Winter Meteorology of Egypt and its Influence on Disease, H. E. Leigh Canney, 52
Les Fours Electriques et leurs Applications, Ad. Minet, 53
Bibliography of X-Ray Literature and Research (1896–97), 53
Die Meteoriten in Sammlungen und ihre Literatur, nebst einem Versuch den Tauschwert der Meteoriten zu bestimmen, Dr. E. A. Wülfing, 53
Volcanoes of North America, Israel C. Russell, 73
Das Princip der Erhaltung der Energie und seine Anwendung in der Naturlehre, Hans Januschke, Prof. G. H. Bryan, F.R.S., 74
The Fertility of the Land, I. P. Roberts, 75
Crime and Criminals, J. Sanderson Christison, 75
Chauncy Maples, 76
Les Ballons-Sondes, M. de Fonvielle, 76
A Geological Map of the Southern Transvaal, F. H. Hatch, 77
Untersuchungen über das Erfrieren der Pflanzen, Prof. Dr. Hans Molisch, 77
Random Shots at Birds and Men, Jim Crow, 77

Stone Implements, the Ancient Weapons and Ornaments of Great Britain, Sir John Evans, K.C.B., 290

Stoney (Dr. Johnston), the Atmosphere of Planets, 207

Storer (Prof. F. H.), Chemical Substances in Tree-Trunks, 15; Agriculture in some of its Relations in Chemistry, 292

Storm, a Magnetic, Dr. Charles Chree, F.R.S., 492

Storm and Sunshine in the Dales, P. H. Lockwood, 463

Storm-Signals used by Various Nations, 59

Straneo (Paolo), Thermal Conductivity of Ice, 157

Stratonoff (Dr. W.), the Movement of Solar Faculæ, 591

Stratton (Prof. G. M.), Experiment in Inverted Vision, 372

Straw, Oat, Wheat, and Rye, M. Balland, 239

Stricker (Prof. Salomon), Death of, 565

Stridulation in some African Spiders, R. I. Pocock, 356

Strohmer (F.), Light and Beetroot Sugar Production, 159

Stromboli, the Volcanic Condition of, E. O. Hovey, 100

Stroud and Barr "Range-Finder," the, 23

Stroud (Prof.), a Folometer and Spherometer, 23

Stroud (S. W.), a New Harmonic Analyser, 333

Stumpe (Dr. Oscar), Death of, 280; Obituary Notice of, 299

Styffe (Prof.), Death and Obituary Notice of, 371

Sub-Oceanic Terraces and River Valleys of the Bay of Biscay, Prof. Edward Hull, F.R.S., 582

Submarine Cable-Testing, Student's Guide to, H. K. C. Fisher and J. C. H. Darby, 459

Submerged River Valleys and Escarpments off the British Coast, Prof. Edward Hull, F.R.S., 484

Substance, the Living, as such and as Organism, Gwendolen Foulke Andrews, 362

Subterranean Fauna, A. Viré, 301

Sudborough (J. J.), a Proposed Memorial to Prof. Victor Meyer, 80; Formation and Hydrolysis of Esters, 239

Sugar Superior to Fat as Food, A. Chauveau, 503

Sulphur and Selenium, Profs. C. Runge and F. Paschen's Researches on the Spectra of Oxygen, Prof. Arthur Schuster, F.R.S., 320

Sumatra, the Triangulation of, Mr. Muller, 527

Sun, the Total Eclipse of the, 1898, 35, 105, 294, 325, 365; Sir Norman Lockyer, K.C.B., F.R.S., 342; Arrival of Eclipse Parties at Bombay, 230

Sunshine, Comparison of Campbell-Stokes and Jordan Recorders, R. H. Curtis, 118

Sunshine Recorders Compared, R. H. Curtis, 518

Sunshine Holyday, on a, 268

Sunspots and the Weather, A. Macdowall, 16

Sunspots, Theory of, Prof. J. Joly, F.R.S., 239

Sunspots, Level of, 284

Sunstroke an Infectious Disease, Dr. L. Sambon, 516

Suprarenal Capsules, Further Observations upon the Comparative Physiology of the, B. Moore, 238; Dr. Swale Vincent, 238, 304

Suprarenal Capsules, Effects of Extirpation of, in Eel, no Existence of Suprarenal Medulla in Teleostean Fishes, Dr. Swale Vincent, 429

Surgery: the Röntgen Rays and Gun-shot Wounds, 102; X-Ray Apparatus for Precise Determination of Position of Projectiles in Cranium, MM. Remy and Contremoulins, 120; the First Application of X-Rays to Surgery, General Maurice, 135; *Lupus vulgaris* treated by Röntgen Rays, 589; Masters of Medicine, John Hunter, Stephen Paget, 194; a System of Medicine, 241; Death and Obituary Notice of Ernest Hart, 251

Suringar (Prof.), the Melocacti, 95

Survey of India, the; Report for 1896, 302

Surveying: Babylonian Land Surveying, Prof. Hamma, 281; the Triangulation of Sumatra, Mr. Muller, 527; Photographic Surveying, Prof. E. J. Mills, 563

Sutherland (A.), the Temperatures of Reptiles, Monotremes, and Marsupials, 67

Swan (J. W., F.R.S.), the Electro-Chemical Industries, 284

Swedish Expedition to the Arctic Regions, a Proposed, Dr. A. G. Nathorst, 163

Sweet (G.), Evidence of Glacial Action in Bacchus Marsh District, Australia, 495

Swinton (A. A. C.), Circulation of Gaseous Matter in Crookes' Tube, 525

Sydney, Report of Australian Museum, 15

Symons's Monthly Meteorological Magazine, 92, 237, 405, 524

System of Medicine, a, 241

Tailless Batrachians of Europe, the, G. A. Boulenger, F.R.S., 577

Tambe (Gopal R.), Mechanism of Self-fertilisation in the Banana, 510
Tanganyika, Lake, Zoological Evidence of Connection with Sea of, J. E. S. Moore, 476
Tappeiner (D. H.), Introduction to Chemical Methods of Clinical Diagnosis, 436
Tarr (Ralph S.), First Book of Physical Geography, 268
Taschenberg (Dr. E. L.), Death and Obituary Notice of, 300
Tayler (F. B.). Relation of Champlain Submergence to Great Lakes and Niagara, 573
Tea Planting and Manufacture, a Text-Book of, David Crole, 97
Teall (J. J. H., F.R.S.), Phosphatised Trachyte from Clipperton Atoll, 502
Teall (Mr.), the Lava Sheets of Franz Josef Land, 324
Technical Education: International Congress on Technical Education, 9; Progress of Technical Education, 259; Analytic Geometry for Technical Schools and Colleges, P. A. Lambert, 292; the Duke of Devonshire on Technical Education, 330
Technological Examinations, Report on, 40
Technology, Brighton Municipal School of Science and, 285
Telegraphy by Circuit, Dr. Slaby, 589
Telegraphy, New Coherer for Wireless, Dr. H. Rupp, 612
Telescopes: New Form of Mirror for a Reflecting Telescope, 160; Large Refracting and Reflecting Telescopes, W. J. S. Lockyer, 200; a Large Reflecting Telescope, Rev. John Peate, 400
Telescopic Seeing, 36
Temperature, Effect of, on Hibernation of Injurious Insects, Dr. L. O. Howard, 85
Temperature, Note on the Influence of very Low, on the Germinative Power of Seeds, Horace T. Brown, F.R.S., 138, 150; F. Escombe, 138
Temperature, Mr. Merrifield's Experiments on the Relation of, to Variation, Dr. F. A. Dixey, 184
Temperature, Thermometrical Determinations of, Likely Sources of Error in, Dr. Hergesell, 469, 470
Temperature of Water, the Critical, H. M. Martin, 80; S. Geoghegan, 101
Temperatures of Reptiles, Monotremes, and Marsupials, A. Sutherland, 67
Temples, Greek, the Orientation of, F. C. Penrose, F.R.S., 151
Tenerife, Observations on the Peak of, Prof. T. C. Porter, 454
Tepotzlan, the Temple Pyramid of, Dr. E. Seler, 551
Termite Mounds of Australia, Remarkable, W. Saville-Kent, 81
Terre (M.), Tuberculosis and Pseudo-Tuberculosis, 407
Terrestrial Magnetism, Recent Researches on, Prof. A. W. Rücker, F.R.S., 160, 180
Terrestrial Physics in Australsaia, P. Baracchi, 493
Tesla Oscillator, a, 335
Test for Divisibility, a, Henry T. Burgess, 8, 30, 55; Dr. C. Börgen, 54; a Correction, 136
Thaxter (Roland), Contributions towards a Monograph of the *Laboulbeniaceæ*, 620
Theory of Electricity and Magnetism; being Lectures on Mathematical Physics, the, A. G. Webster, 49
Therapeutics; Lectures on the Action of Medicine, Dr. Lauder Brunton, F.R.S., 26; the Grape-Cure, 58; Therapeutic Action of Spermine, Alex. Pœhl, 168
Thermodynamics deduced from Motivity, Lord Kelvin, 575
Thermometers, Lord Kelvin's Absolute Method of Graduating, J. Rose-Innes, 166
Thermometrical Determinations of Temperature, Likely Sources of Error in, Dr. Hergesell, 469, 470

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

"*To the solid ground*
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

THURSDAY, NOVEMBER 4, 1897.

MIMICRY IN BUTTERFLIES AND MOTHS.

Researches on Mimicry on the Basis of a Natural Classification of the Papilionidæ. Part ii. *Researches on Mimicry.* By the late Dr. Erich Haase, Director of the Royal Siamese Museum in Bangkok. Translated by C. M. Child, Ph.D. Pp. 154 and 8 coloured plates. (Stuttgart: Ernin Nägele. London: Baillière, Tindall, and Cox, 1896.)

IT is, in some respects, a matter for regret that this important and painstaking work has appeared. The treatment falls far short of the pretensions of the author, and is marred by numerous grave imperfections; and yet the plan is so comprehensive, and the amount of valuable detail so great, that the appearance of a better work will probably be long delayed. The detail which forms the real merit of the work is piled together in a most inartistic manner, so that every reader, except the serious and determined student of the subject, cannot fail to be repelled, and even to the latter the task will be most tedious. And yet there is no subject which is capable of being made more interesting and attractive—alike to the beginner and the advanced student—than mimicry.

The volume deals with mimicry wherever it is found in organic life, beginning with a brief mention of it among flowering plants, and then giving a short account of its occurrence in Arachnida, Orthoptera, Hemiptera, Hymenoptera, Neuroptera, and Coleoptera. It is then treated at great length and detail in the Lepidoptera, the subject being divided on a geographical basis into the models and mimetic forms of (1) the Indo-Australian, (2) the African, (3) the Nearctic, and (4) the Neotropical regions. The mimicry of Coleoptera and Hymenoptera by Lepidoptera is next briefly considered; then follows a short account of mimicry in Diptera, Mollusca, Batrachia, and Reptilia (of the four above-named regions), Birds and Mammals. The memoir concludes with an important general section, dealing in various sub-sections with the history and origin of mimicry in Lepidoptera, and the objections which have been raised against it, and with the biological significance of mimicry in the animal kingdom and its relation to other forms of protective adaptation to the environment.

The vast display of facts and details upon all points prepares a reader to believe that the speculative part of the work will be marked by extreme caution, and guarded by the most scrupulous regard for all available evidence. When, however, the author does begin to speculate, he shakes off all restraint, and indeed in most cases all prudence, and makes the rashest suggestions as calmly as if they were well supported. Good examples of this are to be found in most of his confident statements as regards the past history of the warning and mimetic groups in the Neotropical region (pp. 116–119); in the calm assertion that the variations which have been developed into mimicry were due to "an unfavourable condition of the species, which would cause variations among the females"; in the conclusion, for which the most inadequate evidence is offered, that "the development of the *Neotropinæ* has reached and passed its maximum" (p. 118). We do not often meet with this combination of rash speculation with an almost tedious collection and heaping together of facts, in English works, perhaps because we are less patient in the latter, rather than more cautious in the former.

One very irritating feature of the work is the positive statement of conclusions without any recognition or discussion of the obvious difficulties which they encounter. Thus Haase's contention that what he calls the *Melinæa* type of colouring—

> "may be regarded as a characteristic expression of the special, purely physical and chemical influences of the Neotropic climate on a type of colouring originally black and white"—

is opposed by the want of evidence that effects so produced are hereditary—a difficulty which, at least, merits consideration. Very similar, and even more annoying, are the confident statements which are upset by other statements in a different part of the work. Thus, on p. 138 we are told in spaced type that "in all species which are mimetic in both sexes the female resembles the model more closely than does the male"; while in other parts the author admits the existence of large groups in which both sexes are equally mimetic. Again, his frequently-stated dictum, that mimicry begins with the female, is controverted by the subsequent admission that he is unable to offer any sufficient proofs of it in some of the most important groups.

The author has the most extraordinarily exaggerated notions of the importance of his own contributions to the subject, and he frequently speaks as if he were one of its pioneers, and, with cool assurance, ranges himself beside Bates and Wallace, or more frequently himself claims the credit for work which they had long before accomplished. Thus, on p. 93 he speaks of

> "the fact which I have so firmly established, viz. *that all mimetic modifications appear first in the female, this sex being so much more important than the male for the preservation of the species.*"

In the first place, this principle is by no means firmly established as of universal occurrence; in the second, all that is really true in the statement was brought forward long ago by Wallace. Again, on p. 100 he states with all the insistence of spaced type:

> "Through my observations in Siam I have arrived at the general conclusion that those larvæ which conceal themselves most carefully or show the most perfect protective adaptation are probably those most sought by their enemies on account of their especial edible qualities."

By this unjustifiable or, accepting the most favourable interpretation, ignorant claim to a principle enunciated many years ago by Wallace, Haase puts in a most unfavourable light the really useful work which he has done in the comparatively humble position of a supporter of a well-established and thoroughly accepted conclusion.

Again, on p. 123 he calmly appropriates a principle which we owe to Bates:

> "Thus, we find in these cases also a confirmation of our principle that it is always the rarer immune species which mimics the more common form in order to escape pursuit in its swarms."

The examples quoted above sink, however, into insignificance beside the passage which opens the section "Objections to the Theory of Mimicry" on p. 123: "The attacks on the hypothesis held by Bates, Wallace and myself, viz. that mimicry is the result of natural selection, &c." Having gone so far, Haase was no doubt astonished at his own self-effacement in thus placing his name after the distinguished naturalists to whom we are really indebted for something more than a patient accumulation of facts. Others will, however, feel that it is a piece of sheer impudence for Haase thus to range his name beside the pioneers of the subject to the exclusion of their true compeers Fritz Müller and Roland Trimen.

For a keen naturalist possessing a wide acquaintance with insect form and insect life, Haase shows a strange want of grasp of the well-known principles which operate among living beings in the natural state. Thus he continually speaks as if the protective qualities which accompany a warning appearance confer absolute immunity—an immunity as complete for the larva against the attacks of parasites as for the imago against insect-eating enemies. The term "immunity" ought not to be used at all with regard to these forms, unless very carefully qualified. Such a heading as that on p. 96, "Origin of Mimicry between Non-immune and Immune Lepidoptera," is liable to convey a very false impression of the facts of nature. We may feel confident that the average ratio of extinction to survival is the same in both groups—that a pair of the so-called immune species, in spite of all their numerous progeny, are upon the average succeeded by a pair only. The warning colours and the qualities they imply do indeed secure a high degree of immunity from the attacks of certain enemies, especially during certain stages, but other enemies have acquired the hardihood necessary to make use of the abundant and easily captured prey. So far from accepting Haase's dictum (p. 97) that

> "it is certain that the early stages of immune butterflies suffer in general less from parasites than those of other Lepidoptera,"

we may feel confident that the reverse is the truth. Haase brings before us an unworkable theory according to which the species with warning colours must continue to increase in numbers, indefinitely from generation to generation. No doubt at the very origin of this special means of defence the species concerned were enabled to increase largely in numbers, and very many of them have reached a condition of equilibrium as abundant and dominant species. But as soon as this equilibrium is reached there is no interference in the general law that the amount of extinction keeps down the numbers of the species to a certain average; and we may therefore feel sure that the relative immunity from the attacks of certain enemies, and during certain stages, is compensated by the excessive attacks of other enemies, and during other stages; and furthermore, that during the progressive growth of the numbers of the species, each increase was attended by increased attacks until equilibrium was reached. Haase depicts a state of affairs which would cause an indefinite increase, and could lead to nothing but the extinction of the food-plant, and consequently the disappearance of the species. The keen observation of Belt detected some of the ways in which the numbers of unpalatable butterflies are kept down; for he noticed a flower-haunting spider which eagerly devoured them, and a wasp which stored them up in its nest. In order to support his views of extreme immunity, Haase makes, as regards these observations of Belt, the absurd suggestion that "it is perhaps possible that the mimic was mistaken for the model."

Haase shows a similar want of insight in his contention that mimicry and protective resemblance arose in a time of great struggle which has now ceased to exist. He concludes his work in these words:

> "It is probable that all these resemblances to the moving or motionless and the living or lifeless environment have arisen in the interest of the preservation of the species from extinction during periods when the struggle for existence was most bitter, and from chance variations which corresponded to this purpose and whose further development was aided by natural selection and fixed by inheritance. Under these circumstances it appears then, to close with the apt words of Brauer, that 'the struggle for existence being ended, the forms reach a state of equilibrium, and the living species (being under the same conditions) are preserved from extinction.'"

All this is the most utter folly; the struggle for existence is now what it has ever been, fluctuating in degree, but always severe, and we know that when a species is shielded from the struggle as regards any part of its organisation, that part is very far from maintaining an equilibrium unchanged.

The suggestion that the unpalatable qualities are due to the juices of the food-plant of the larva has often been made before, but never with so much insistence as in Haase's work. He quotes a number of cases in support of his contention, and neglects those which oppose it. Haase would apparently deny to insect physiology the power to construct a protective odour or flavour, although the laboratory of an insect's body has been shown to be a marvellous workshop producing all kinds of unexpected compounds, and although the food-plants of many of the commoner of our distasteful European moths do not belong to any poisonous or acrid category. Although it is possible that the noxious or nauseous qualities may, in certain instances, be borrowed ready-made from plants, such an origin is as yet unproved; while its universality, as assumed by Haase, has been effectually disproved.

For a work of such great pretensions the want of a wide and adequate acquaintance with other writers is somewhat remarkable. Thus Dixey's memoir on the Phylogeny of the wing-markings of Vanessidæ and Argynnidæ, as well as that on the Pierinæ should have been consulted; for the author often attempts to reason upon the same lines, without having devoted any special study to the subject. In speaking of the different forms of the female of *Papilio merope* (*cenea*) he states (pp. 45, 46) that Mansell Weale *captured* a large number. In reality, the evidence supplied in support of Trimen's argument that these different forms were the females of a single species with a very different male, was of a far more satisfactory kind; for Mansell Weale *bred* all the forms as well as the male from larvæ taken upon a single tree. Furthermore, no account of this most remarkable case can be regarded as adequate without a detailed reference to Trimen's classical paper. The reference is here and on p. 104 of the most meagre and unsatisfactory kind. Again, there is no allusion to Westwood in the account of the early history of the subject, or to Gahan in the account of mimicry in Coleoptera (p. 131). In his consideration of the classification of mimicry, warning colours, &c., suggested by the present writer, the author is satisfied with the study of a second-hand account of an easily accessible work.

Again, on p. 123, Haase states that Wallace, as well as Fritz Müller, originated the explanation of resemblance between inedible species and genera. As a matter of fact, we owe to Fritz Müller alone the important suggestion that forms which resemble each other and thus combine their advertisements, so to speak, are recognised with a smaller expenditure of lives than those which possess independent advertisements, each of which requires to be learnt separately. The fact of such resemblance was first recognised by Bates, but its explanation remained a difficulty under the theory of mimicry which we received from him. Wallace freely acknowledged the debt which we owe to Fritz Müller, and at once saw the great and far-reaching importance of the new suggestion. One great fault of the present work is the failure to recognise this importance, and the attempt to explain nearly all cases on the lines of Bates' theory of specially protected model and defenceless mimic, instead of constantly introducing the useful conception of resemblance for mutual advantage between specially protected species and groups.

Thus, to take but a single example, the treatment of the resemblances of the Erycinidæ (pp. 61, 62), as well as that of some of the Pierine genera, would have received much light from the Müllerian standpoint.

On p. 134 the distinction between protective and aggressive mimicry is ascribed to the present writer, although it was made by many writers long before he contributed anything to the subject. Having made this error, Haase goes on to criticise the cases included under the latter term, stating that "the disguise itself always serves only as a means of protection, and never as a weapon of attack, even when borne by the aggressors." He then proceeds to destroy his own criticism by citing several cases (p. 135) in which he maintains that the resemblance does act as a weapon of attack. It is to be hoped that the translator is to some extent responsible for this tissue of mistake and self-contradiction. At the moment of writing, access to the German original is impossible.

There are a number of errors in the systematic part of the work which we should hardly expect to see. Thus the name *Hypolimnas bolina* (L.) is given when *H. misippus* (L.) is intended (p. 41), and the appearance of the type form is wrongly ascribed to the var. *inaria* (Cr.), although this may be a mistake of the translator. In Plate xi. (Fig. 76) an *Anthomyza* is described as a *Hyelosia*, and in the same plate an undoubted representation of *Methona confusa* (Butl.) in Fig. 78, is stated to be *Thyridia psidii* of Linnæus, the author being careful to add the words "not *Methona*" after the generic name. There has been much confusion between these two closely convergent, although in reality widely different species—so much so indeed that even Bates was deceived—but the account given by Godman and Salvin in the "Biologia" places the matter on a secure basis, and clearly shows that the Linnean species is *Thyridia psidii*, possessing white spots on the black border of the hind wing. The latter species is also distinguished by a small reddish spot at the base of the fore wing; and both these characteristics being absent from Fig. 78, we can only conclude that it represents the species of *Methona* from which they are also absent. A very unaccountable error is the positive statement (p. 145, *note*) that there are no "unmistakably mimetic species" among the Lepidoptera of Madagascar. The author must surely have been aware of the occurrence of *Hypolimnas misippus* (L.) in that island. In the same note the impression is conveyed that there is a widespread belief that isolation, as in islands, rather than the keener competition of continental areas, favours mimetic modification; and Haase apparently takes some credit to himself in supporting the opposite view. But the ancestral character of island faunas in relation to mimicry was recognised long before the appearance of Haase's work, and has never been seriously disputed.

Another obvious error occurs on pp. 147, 148, where the resemblance of the *imagos* and not the *larvæ*, as stated, of *Calocampa exoleta*, &c., to sticks, is intended. One is at a loss to understand why some ancestral time at which Haase imagined that food was especially scarce, and the enemies of insects especially keen, should be spoken of as a "Palæolithic Period" (p. 118).

At the end of the volume the author contributes a section, entitled "Mimicry a form of protective adaptation to the environment" (pp. 145-151). In these pages he treats, in a very inadequate manner, of protective resemblances in general. The important and widespread cases of variable colour resemblances he does not even mention. The attempt is made to distinguish between protective resemblance and mimicry on the ground that the latter is an imitation of moving objects, the former of motionless ones. This distinction, which has been drawn before, seems to the present writer to be unreal, and, so far as it holds, to be of little importance as a basis for classification. There are many examples of the protective resemblance of moving objects —butterflies and moths which resemble leaves whirled along by the wind; larvæ and cocoons which resemble sticks, &c., swinging by a thread. The essential distinction lies in the fact that in protective resemblance the model is of no interest to the enemies of the imitator, while in protective mimicry the model is dreaded or disliked by the enemies; the effect of protective resemblance is concealment; the effect of protective mimicry, conspicuousness.

In this section the wonderful resemblance of butterflies of the genus *Kallima* to dead leaves is briefly discussed, and the author concludes (p. 147) that

> "the extraordinarily manifold variations among *Kallima*, &c., show, not only that these so perfect resemblances of withered leaves, and often of those covered with rust-fungus or partially eaten by larvæ of *Agromyza*, are the highest development of mimicry of leaves, but they also indicate that these are the youngest forms, and are still under the influence of natural selection, which will gradually obliterate that which is less fitting."

It is, of course, very improbable that a species which has attained the highest development in any character could still remain in the formative stage as regards the very same character. As a matter of fact, the "extraordinarily manifold variations" of *Kallima* are not the ordinary individual differences upon which natural selection acts, but rather certain varied forms into which the species has been thrown by natural selection, causing it to resemble not one, but many of the appearances presented by dead leaves, and thus conducing towards its protection. This high product of selective action has been mistaken by Haase for the mere material for selection to begin its work upon.

There are some excellent pieces of work and interesting suggestive inferences to be found in the memoir—not to be compared to the great hypotheses connected with the names of Bates, Wallace, and Fritz Müller, but valuable additions to the subordinate parts and details of the subject.

Of this kind is the discussion on mimicry in the *Papilioninæ* (pp. 80-95), to which Haase has given special attention, and which forms the subject of Part i. of his work, as yet untranslated into English. In this section he produces evidence that the species of *Papilio* which are especially mimicked by others belong to the genus *Pharmacophagus*, and, as he thinks, derive their qualities from the poisonous or acrid larval food.

The contention (p. 97) that specially protected butterflies but rarely avail themselves of a distinct and markedly conspicuous "warning colour," that "among the *Neotropinæ* in general the wing-colouring, with its brilliant yellow, rusty-brown and black, is more beautiful than unpleasant," must be admitted to be true; the conclusion was, in fact, stated in 1890 by the present writer, who also pointed out that a conspicuous appearance is nevertheless attained because "the colours spread on the parts which are exposed during rest, and the flight becomes sluggish, so that they are displayed as completely as possible" ("Colours of Animals," Lond., 1890, p. 191).

On p. 106 we meet with an interesting case (that of four white spots on the outer margin of the hind wing of the female var. *protogenia* of *Elymnias undularis*, Dru.), in which it is argued with force that changes caused by reversion to an older type of marking have been made use of to aid a mimetic resemblance. In a note on the same page, Haase brings forward *Cethosia cyane*, Dru., as a unique example of a closer resemblance on the part of the male than the female to another specially defended insect—*Danais chrysippus*. He makes the very probable suggestion that the *Cethosia* is also itself specially defended.

Interspersed with much almost worthless speculation there is a great deal that is suggestive and valuable in the analysis of the various patterns of those *Neotropinæ* which are resembled by other butterflies, including many belonging to different sections of the group itself (pp. 116, 117). The various tables embody an immense amount of careful comparison and the examination of a vast number of specimens; they will prove of the highest value to future workers. E. B. P.

(*To be continued.*)

A DEVONSHIRE GEOLOGIST.

A Memoir of William Pengelly, of Torquay, F.R.S., Geologist, with a Selection from his Correspondence. Edited by his daughter, Hester Pengelly. With a summary of his scientific work, by the Rev. Prof. Bonney, F.R.S. 8vo. Pp. xi + 341; with portrait and 10 illustrations. (London: John Murray, 1897.)

THE story of William Pengelly is one of the pursuit of knowledge under difficulties, and of the achievement by the hero of an honoured place amongst those who have rendered distinguished service to science. Many of his paternal ancestors were sailors, and his father was captain of a small coasting vessel, in which his son William accompanied him, after receiving an elementary education at East Looe in Cornwall. For four years the lad was engaged in a seafaring life, but in 1828, at the age of sixteen, and at the earnest desire of his mother, he returned to his native village, and was occupied for a few years in active manual labour. He had, however, developed a passion for learning, and every hour that could be spared, was devoted to the acquisition of knowledge, and more especially of mathematics. Having so far prepared himself, after severe study and under great privations, for more congenial labours, he removed to Torquay and opened a small day-school. Here he met with good success, which rapidly increased as the years passed by.

His earliest geological lesson had been learned at Lyme Regis when, as a sailor boy, he had been weather-bound on the Dorset coast, and had observed a fine ammonite. Later on the reading of a chapter on geology in a work published by the brothers Chambers, gave him his first insight into the objects of the science, and led him to devote attention to the subject. Thus, when he went to London in 1843, he was interested in visiting the British Museum, the Royal College of Surgeons, and the Museum of Economic Geology (as it was then called) at Craig's Court. He had some difficulty in finding the last-named museum.

Torquay has always been a locality of great interest to the geologist, and when Pengelly commenced his labours it was not long after the founding of the Devonian system by Sedgwick and Murchison, aided by Lonsdale. Moreover, De la Beche and Godwin-Austen had published their important researches on South Devon, and McEnery had brought into notice the interest attaching to the local bone-caves. No wonder that Pengelly, when once his ardour had been kindled, started to explore the district with vigour and enthusiasm.

Many little adventures and anecdotes are recorded with reference to his geological expeditions. On one occasion at a wayside inn, where he had taken a seat on the kitchen settle, Pengelly answered some inquiries addressed to him by three labourers, and finally entertained them to such good effect on the subject of stone-breaking, that the landlord became keenly interested. Seeking an interview next morning with Pengelly, he thus expressed himself:

"I hope no offence, sir: but ef you'd stop 'ere for a foo days, or a week, and talk to the men in the evenin's, you shud be welcome to meat, drink, washing, and lodging free gratis. I'm sure lots o' men wud come an' hear 'ee, and I should zell an uncommon zight o' beer."

In 1855 Pengelly went, for the first time in London, to an evening meeting of the Geological Society. In a letter to his wife he says:

"There were probably about forty persons present, which I believe is considered a good attendance. We were rather late, and found on our arrival that a paper was being read descriptive of Mauna Loa, the volcano in Owhyhee. At its close, Austen, a well-known geologist, and who once lived at East Ogwell, read a paper on the 'Probability of coal existing at workable depths near London.' . . . A discussion followed the paper, in which the author was by no means spared, as the various speakers expressed themselves freely."

What seems remarkable to us is the small attendance at the reading of this important paper by Godwin-Austen, and the fact that it was given second place at the meeting! Next year Pengelly attended another meeting of the Geological Society, when papers were read by Carrick Moore and Babbage. He says, "It was a magnificent meeting, and made me wish for a town residence."

Pengelly first attended the British Association in 1856, at Cheltenham, and he was present at all subsequent meetings up to 1889, with the exception of that held at Montreal in 1884.

In 1858 his detailed researches on the caverns of Devonshire may be said to have commenced. In that year the Brixham Bone-cavern was discovered, and the investigation was undertaken by the Royal and Geological Societies; a committee being appointed by the latter body, and the exploration being placed under the superintendence of Mr. (afterwards Sir Joseph) Prestwich and Mr. Pengelly. The bulk of the work naturally fell to Pengelly. It was long before the results of this investigation were issued. The delay, indeed, was aggravating, for it was not until 1873 that the full account was published.

Meanwhile Pengelly became engaged in a systematic examination of the lignites and clays of Bovey Tracey, in conjunction with Dr. Oswald Heer, who undertook the determination of the plant-remains. This important work was executed at the expense of the Baroness Burdett-Coutts, and the results were published in 1862. The age of the deposit was regarded by Heer as Miocene, but it has since been shown by Mr. Starkie Gardner to be Eocene.

In 1864 the first steps were taken to secure a systematic exploration of Kent's Hole, Torquay; and, aided by grants from the British Association, the work was carried out by Pengelly, who for more than fifteen years devoted himself with never-flagging energy to the task. During these years he annually reported progress at the meetings of the British Association, and his discourses on these occasions formed an attractive feature in the proceedings of Section C. Here, as elsewhere in all his lectures, he contrived to blend his science with a considerable amount of humour, while his expositions were both clear and spirited.

With regard to the exploration of Kent's Hole, Prof. Bonney rightly observes that "it was the most complete and systematic investigation of a cavern which had ever been undertaken." The time and labour, the care and patience, exhibited by Pengelly, and the precision with which he noted every fact, were extraordinary, but thoroughly characteristic of the man. His very full reports will ever remain as a monument of these labours. He had intended to publish a separate book on Kent's Cavern; but, considering that all particulars have been given in his many papers, the abandonment of this task need not seriously be regretted.

This outline of his principal work affords but a meagre idea of the activity of the man. He not only spent a good deal of time in lecturing in many provincial towns, but devoted much energy to local institutions in Torquay. The organic remains from various formations in Devonshire were eagerly sought for, and a fine collection of Devonian fossils which he had gathered together was presented to the Oxford Museum by the Baroness Burdett-Coutts in 1860.

His main efforts were always directed to the geological questions relating to Devon and Cornwall. He was master of all the literature, and many of his contributions were most useful summaries of knowledge on particular subjects. Curiously enough, but little is said in this volume of his fellow-workers in Devonshire. Dr. Harvey B. Holl, who, after Godwin-Austen, published a detailed account of the geology of South Devon, is not mentioned. Nor is much said of G. W. Ormerod nor of A. Champernowne, the latter of whom had laboured more assiduously than any previous worker at the intimate structure of parts of South Devon. More frequent references are made to William Vicary, who happily survives, and whose grand collection has done so much to illustrate the life-history of the rocks of Devonshire; and there are several references to John Edward Lee, though not to his collection of Devonian fossils, perhaps the finest of its kind as regards South Devon. Such omissions may not be deemed of great importance, but to one not familiar with the subject the book is apt to convey the notion that Pengelly was almost the sole worker, in his time, on Devonshire geology.

A great portion of the volume is taken up with letters from Pengelly to various members of his family, giving interesting accounts of his journeys and lectures, and of the many men of science and others whom he met; and there are numerous extracts from letters of Lyell and others addressed to Pengelly. The fame of Kent's Cavern brought many an illustrious visitor to Torquay, and although Pengelly's time was a good deal taken up in describing the cavern and its contents, he was naturally gratified at the interest manifested. In society he was always a genial companion, full of fun, and notoriously full of puns; so much so indeed that in 1862, at the first meeting of the Devonshire Association, which he was mainly instrumental in founding, he was christened Mr. *Pun*gelly by the President, Sir John Bowring.

Prof. Bonney, in a concluding chapter, has given a capital account of the scientific work of Pengelly; and appended to it is a list of his papers, apparently compiled from the Royal Society "Catalogue of Scientific Papers." Unfortunately these are not enumerated in strict chronological order, nor is the list complete. It would have been well to make it so, for it would have been an appropriate record of Pengelly's many-sided labours. One of his elaborate papers, published in the *Transactions* of the Devonshire Association (vol. v.), dealt with "The signs of the hotels, taverns, inns, wine and spirit vaults, and beershops in Devonshire"—a subject that should not be without interest to the field-geologist.

Those who were personally acquainted with Mr. Pengelly will read this work with especial interest, including the accounts of many minor circumstances that otherwise may appear somewhat trivial and unnecessary. When, however, we remember that the work has been edited by the loving hand of a daughter, we may well pardon any excess of zeal, and thank her for having given so excellent a biography of one who laboured manfully, enthusiastically, and successfully in the cause of science.

MEXICAN ARCHÆOLOGY.

Archeological Studies among the Ancient Cities of Mexico. Part ii. By W. H. Holmes. Pp. 200. (Chicago, 1897.)

THE second part of Mr. Holmes' work on the ancient cities of Mexico has this year appeared, and completes the first part of a series of anthropological publications to be produced under the auspices of the Field Columbian Museum at Chicago. This work, extending as it does to over 300 pp. and containing numerous plans, sketch-maps, drawings and photographic reproductions, has been conceived on a somewhat more ambitious scale than previous publications of the Field Columbian Museum. It is evident at a glance that the greatest pains have been taken in the preparation of the plans and drawings, while the numerous papers Mr. Holmes has already contributed to various scientific journals are a sufficient guarantee of his competence to undertake a survey of one or more of the cities of ancient Mexico. In this field of archæological research there are already many patient workers who devote much time to the excavation and survey of the ruins, but there is no lack of material for study, and many sites still remain comparatively untouched. We must admit, however, that the two parts before us are a little disappointing. From the obvious care expended on them we were prepared to welcome them as a contribution of the first importance to Mexican archæology, but on perusal they do not quite justify our expectations. Let us hasten to add that this is due to no fault of the author, but is a necessary consequence of the plan and nature of the expedition of which the volumes are a record.

Mr. Holmes' studies among these ancient sites were undertaken in the spring of 1895, when he spent three months travelling in these regions with Mr. A. V. Armour, of Chicago, and other friends. Botany, geology, anthropology and natural history were impartially studied by the party, and, as Mr. Holmes remarks in his preface, he himself as "Curator of Anthropology" in the Field Columbian Museum, "was expected to examine and describe such archeologic remains as happened to be encountered during the journey." It must not, however, be supposed that the book is merely the record of a pleasure trip. The localities visited are dealt with systematically, but in every case too little time was given to the examination and measurement of the ruins. The first part of the trip was devoted to the monuments of Yucatan, when the islands of Contoy, Mugeres, Cancun and Cozumel, and the mainland opposite them, were examined in less than two weeks, during which period the party went as far south as Tuloom, where they did not land, but Mr. Holmes sketched the ruins from the sea. In the interior of Yucatan the remains at Tikul, Uxmal, Izamal and Chichen-Itza were also examined in less than a fortnight. The first part of the book dealt with these places, but it will be obvious that so little time having been spent at the actual ruins, Mr. Holmes' notes were necessarily superficial. He thereby lays himself open to correction by more systematic explorers than himself, and, as a matter of fact, Mr. Alfred P. Maudslay, who in 1889 encamped for five months at Chichen-Itza, which Mr. Holmes and his party in 1895 did in a week, has already pointed out in the columns of NATURE (vol. liv. pp. 274 *ff.*) several inaccuracies in his observations. The second part of the work, which has just appeared, deals with the monuments of Chiapas, Oaxaca, and the Valley of Mexico, and though larger in bulk than its predecessor, represents the result of observations made in an even shorter period, four days being spent on the ruins of Palenque, a week at Mitla, a day on Monte Alban, while from Mexico two brief excursions were made to San

Juan Teotihuacan. It is needless to point out that this publication could not have been compiled had the places never been surveyed and described by other explorers. Mr. Holmes frankly admits that his work is no more than a sketch of the sites he visited "seen at a passing glance"; but even regarded merely as an introduction to the study of Mexican archæology, its value to the student would have been much increased by the inclusion of references to the extensive literature on the subject, and by a discussion of the work accomplished by previous explorers and archæologists.

OUR BOOK SHELF.

Manuale del Chimico e dell' Industriale. By Prof. Dr. Luigi Gabba. Pp. xvi + 442. (Milan: Ulrico Hoepli, 1898.)

La Fabbricazione dell' Acido Solforico, dell' Acido Nitrico, del Solfato Sodico, dell' Acido Muriatico. By Dr. V. Vender. Pp. v + 312. (Milan: Ulrico Hoepli, 1898.)

Leghe Metalliche ed Amalgame. By I. Ghersi. Pp. xii + 431. (Milan: Ulrico Hoepli, 1898.)

THE three volumes, the titles of which are given above, belong to an extensive series of manuals published by the firm of Hoepli, Milan. More than five hundred of these Manuali Hoepli have now been published, covering a variety of subjects in science, letters, arts, and industries.

Prof. Gabba's volume is a collection of tables of physical and chemical data, and of analytical processes, for the use of analytical and technical chemists, directors of chemical works, students of chemistry, and others. The tables and the descriptions of methods of detecting various substances, and of carrying out a complete analysis or assay, will be found very serviceable to all technical chemists. The volume contains a mass of physical and chemical data, and it will prove as useful to analysts as engineering pocket-books are to engineers.

Dr. V. Vender's work on the manufacture of sulphuric acid, nitric acid, and hydrochloric acid, presents in a concise form the essential facts of these great chemical industries. In the case of each product, the substances employed in its manufacture, the general principle of the manufacture, the theory of the various processes, the details of construction of the plants in use, and methods of analysing the products, are described. The book is instructively illustrated; and though the text is in Italian, English chemists will find that they can read it by occasional reference to a dictionary.

In the third of Hoepli's Manuals referred to at the head of this notice, Signore Ghersi provides metallurgists with a handy book on metallic alloys and amalgams. The volume opens with a description of alloys in general, and then deals in succession with binary alloys, alloys of aluminium with common metals, nickel alloys, amalgams, alloys of gold, silver, and platinum, alloys for coinage and medals, bronzes, brass, ternary and quaternary alloys, Delta metal, fusible alloys, alloys which simulate various metals, and solders. There is an appendix containing useful tables of physical and chemical data referring to alloys, a long list of works cited, and a good index. The author frequently refers to recent investigations of metallurgists in various parts of the world, and his book does credit to him and to the scientific spirit in Italy.

Lectures on Quaternions. Part i. Introductory. By S. Kimura, Sendai, Japan.

WE are unable to read this treatise, because it is printed in Japanese. The mathematical formulæ and woodcuts show that the author is introducing his students to those elementary geometrical (curve and surface) illustrations of the vector calculus (mainly vector addition and differentials) which may be taken up without any knowledge of a quaternion. The characters are printed in horizontal rows instead of the usual vertical columns, and this might be taken as the text for a sermon on the modern changes in Japan. The concession is necessary if a student is to read mathematical formulæ with ease, yet it is one which need not alarm the scholars, and by making it the author takes away an objection to the use of Japanese characters, and so keeps his reader in touch with Japanese literature. Every Japanese reader of such a treatise is well acquainted with English, and if the teaching of mathematical science were to be considered by itself, all such books might just as well be printed in English. But it is well known to all who have studied the Japanese that they are not merely studying our commercial and military and scientific ideas, but how they may assimilate these ideas without undue hurt to their own old civilisation and developed instincts and fine moral character, which seem to them, and indeed to some of us, of a very much higher order than what we find in Europe. Well, the vector calculus can do little harm to anybody; but when Part ii. is published, and the author introduces his quarternions, he may be glad that the old scholars who protect the morals of his country are unable to understand what he is writing about. J. P.

Lehrbuch der Erdkunde für höhere Schulen. By Dr. Willi Ule. I. Theil (Für die unteren Classen). Pp. viii + 176. (Leipzig: G. Freitag, 1897.)

THIS is an excellent reading-book for children, but as it is printed in the German language, it will not be found very useful this side of the Channel. Written in a very simple manner, and dealing only with fundamental ideas, the author describes clearly and concisely the main physical features of the earth—such as mountains, plains, continents, races, &c. Each of the different countries is generally described, and typical illustrations are inserted here and there. Several paragraphs are also devoted to brief general descriptions of the weather, climates, elementary astronomical phenomena, map-drawing, &c. The author has succeeded in bringing together in a methodical and natural sequence a great amount of information which the children will read with delight. Names and numbers have been suppressed as far as possible in the text, these being added in tabular form at the end of each section, more for the use of the teachers than for the readers.

The Great Meteoric Shower of November. By W. F. Denning, F.R.A.S. Pp. 52. (London: Taylor and Francis, 1897.)

UPON the subject of meteor-observation, Mr. Denning teaches "as one having authority, and not as the scribes." This pamphlet, reprinted from the *Observatory*, furnishes meteoric observers with a number of interesting facts as to past November showers of Leonids, and prospects of observations between now and 1905. Mr. Denning deals in succession with the position of the Leonid radiant, the character of the radiant, the visible aspect of the individual Leonids, the real paths of the meteors in our atmosphere, minor meteor showers visible at the Leonid epoch, expected phenomena at the ensuing return, the observations required, and the November shower from Biela's comet. Every astronomical observer should possess a copy of the pamphlet, for the perusal of it will show him exactly what points require attention, and will thus increase the value of his observations.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

A Bee's Movements in a Room.

THE following was communicated to me by a friend of mine, Mr. E. W. Winstanley, of Trinity College, Cambridge, and, as it may have some value respecting the relations of insects to flowers, I think it worth putting on record. The observations were written down on the day after the occurrence, when he related to me the facts, and I reproduce them here in his own words:—

"Sitting reading in my room (15 Jesus Lane) by the open window, about noon, October 21—a sunny day—I became conscious of a buzzing sound, and, on looking up, found it due to the entrance of a bee. Noticing that certain objects seemed to arrest the insect's attention, I paid special heed to its movements. It first went across to the pictures on the opposite wall, following them round the room, and hovering a short time close to each of the coloured ones, then passing out of the door, which was wide open; returning, after a few seconds, it flew straight to the gas-shades, which, two in number, are situated one on each side of the mantelpiece; it lingered over the top of one, and then passed on to the other, and repeated this movement. It now took a second tour of the pictures, and after stopping a moment or two near one of the brass knobs of the curtain-pole, came again to the gas-shades and made a closer investigation of them, both by hovering over the top and by entering at the bottom around the gas-burners. It then visited in succession four ornaments on the mantel-mirror, drew near once more to the large central coloured picture, made a second exit by the door, coming back almost immediately, and, after dwelling near the two small coloured pictures for the third time, flew straight out of the window.

"It never actually alighted anywhere, remaining near the objects by the rapid quiver of its wings. The whole visit the bee paid me occupied probably five minutes or less. Although I did not examine it closely, I considered it to be a hive and not a humble bee."

The special features to notice in the above are the systematic way the bee flew about, and the nature of the objects which attracted its attention.

Any one on surveying the room would admit, I think, that the gas-shades and the pictures are the most brightly coloured things in it.

The gas-shades are semi-opaque, lily-shaped, and tinted from yellow to bright pink upwards; in fact, they resemble very large gamopetalous flowers (corollas).

The pictures in the room numbered seven, consisting of a large frame enclosing five photochrome views, of two small photochromes, and four photogravures. My friend says it was distinctly the coloured ones that attracted the bee, giving the other ones a mere glance, as it were. The photochromes are vividly coloured, blue predominating.

The remaining objects visited, the ornaments, are not striking or large, but have flowers painted on them on a white ground, mostly resembling blue forget-me-nots. My friend was somewhat astonished at the bee regarding these, as he was not aware, till he looked, that the vases were decorated thus. He is not a botanical student, and has no bias towards any theory of the flower; it was the methodical way the bee went about the room that arrested his attention. It is mainly owing to this fact that I thought it worth while to make his observations known. Recently some observers have put forward reasons for considering that the colour of the flower exerts little attraction towards insects, and that it is chiefly the odour. The above piece of information favours decidedly colour attraction. There was no perception of odour, or any flowers or plants present in the room at the time.

To my mind it seems rational to assume that colour and odour may play somewhat equal attractions, the scent serving to bring bees from a distance, and the colour helping to guide them directly to the honey. A bee becoming accustomed to associate nectar with conspicuously coloured objects, might thus learn to visit flowers wholly from colour-sensation, and, not having sufficient discriminating power, visit other brightly-coloured things as well.

J. PARKIN.

A Test for Divisibility.

MAY I venture to supply a long-felt want amongst arithmeticians, viz. a general test of divisibility?

Let N be any integral number, and δ any divisor, then

$$\begin{aligned} N &= a + 10b + 10^2c + \&c. \\ &= a + b(\delta q + r) + c(\delta q + r)^2 + \&c. \\ &= \delta Q + a + br + cr^2 + \&c. \\ &= \delta Q + a + b(\delta q_1 + r_1) + c(\delta q_2 + r_2) + \&c. \\ &= \delta Q + \delta Q_1 + N_1 \\ &= \delta(Q + Q_1) + N_1. \end{aligned}$$

Here N_1 is the least general substitute for N, and is of the form

$$a + br_1 + cr_2 + dr_3 + \&c.$$

where the number of values of r_1, r_2 &c. cannot exceed $\delta - 1$, but may be much fewer, and constitute a recurring series found from

$$\frac{10^n}{\delta}, \text{ where } n = 1, 2, 3, 4 \text{ \&c.}$$

$$\begin{aligned} \text{Let } \delta &= 2, 5, \text{ then } N_1 = a \\ &= 4, \qquad = a + 2b \\ &= 8, \qquad = a + 2b + 4c \\ &= 16, \qquad = a + 10b + 4c + 8d \\ &= 3, 9, \qquad = a + b + c + \&c. \\ &= 7, \qquad = \left.\begin{array}{l} a + 3b + 2c + 6d + 4e + 5f \\ + g + 3h + 2i + 6j + 4k + \&c. \end{array}\right\} \\ &= 37, \qquad = \left.\begin{array}{l} a + 10b + 26c \\ + d + 10e + 26f + \&c. \end{array}\right\} \\ &= 11, \qquad = a + 10b + c \div 10d + \&c. \end{aligned}$$

and so on.

The practical importance of this general test must primarily depend on the brevity of the recurring period of r_n, but in special cases this objection may be removed.

Thus when $\delta = 11$, if $N_1 \div \delta = 11q$ we have

$$\begin{aligned} N_1 &= (a + c + \&c.) + 10(b + d + \&c.) \\ &= S \times 10S_1 = 11q. \end{aligned}$$

But $S - q = 10(q - S_1)$

where $(S - q) \div 10 = q - S = q_1$ suppose;

also $S_1 = (11q - S) \div 10$;

$$\therefore\ S - S_1 = 11\left(\frac{S - q}{10}\right) = 11q_1.$$

That is, the difference of the sums of the alternate series of digits is divisible by 11 if N or N_1 be so divisible. This result may be applied thus: Let a_3, b_3, c_3 &c. denote triple periods, and $\delta = 1001$, then

$$\begin{aligned} N_1 &= a_3 + 10^3b_3 + c_3 + 10^3d_3 + \&c. \\ &= (a_3 + c_3 + \&c.) + 10^3(b_3 + d_3 + \&c.) \\ &= S + 10^3S_1 \text{ which may be changed to} \\ &\quad S - S_1. \end{aligned}$$

Thus $S - S_1$ is a test for divisibility by 7, 11, 13, 77, 91, 143, 1001.

Again, if a_4, b_4, c_4 &c. denote quadruple periods and $\delta = 10,001$, then

$$N_1 = a_4 + 10^4b_4 + c_4 + \&c. = S - S_1$$

and is a test for $\delta = 73, 137, 10001$.

Again, if a_6, b_6, c_6 &c. denote sextuple periods and $\delta = 1,000,001$, then

$N_1 = a_6 + 10^6b_6 + c_6 + \&c. = S - S_1$ and is a test for $\delta = 101$; 9901.

As examples take

(1) $N = 807,929,122$; $\delta = 7, 11, 13, 143, 77, 91$;
$S - S_1 = 122 + 807 - 929 = 0$.
$\therefore$ the proposed number is divisible by δ.
(2) $N = 67, 3558, 3491$; $\delta = 73, 137$.
$S - S_1 = 3491 + 67 - 3558 = 0$.
(3) $N = 360, 4536, 7388$; $\delta = 73$.
$S - S_1 = 7748 - 4536 = 3212 = 73 \times 44$.
(4) $N = 390, 9569$; $\delta = 137$.
$S - S_1 = 9179 = 137 \times 67$.
(5) $N = 585622, 677027$; $\delta = 101$.
$S - S_1 = 91405 = 905 \times 101$.
(6) $N = 954221, 304387$; $\delta = 101$.
$S - S_1 = 649834 = 6434 \times 101$.

When the periods consist of similar groups, as

222, 222;
123, 123;
333, 777, 444;
333555, 333555;
5174, 1399, 1399, 5174;

divisibility by the formula $S - S_1$ may be determined by inspection, and this conclusion will not be modified by like permutations of each group. Thus 123123, 312312, 132132 &c. are each divisible by 7, 11, 13, 91, 143 &c.

Lastly, since r_n changes with every value of δ, no general formula for the determination of primes can exist.

HENRY T. BURGESS.

Tarporley, West Norwood, October 16.

INTERNATIONAL CONGRESS ON TECHNICAL EDUCATION.[1]

IT is difficult to know how best to review a volume consisting of such varied matter as the Report of the Proceedings of an Educational Congress. Even when restricted to technical education, the subjects that may be legitimately discussed are very numerous; and with the constant widening of the definition, it is not easy to exclude any branch of knowledge, as outside the field of inquiry. After reading very carefully the closely-printed volume of nearly 300 pages, which includes the papers *in extenso*, and a summary of the discussions, we must own to some feeling of disappointment at the poverty of the results. Several of the writers and speakers are men of knowledge and experience, who write and speak with authority on their respective subjects; but, nevertheless, the volume before us adds little to what was previously known, and we look in vain through its pages for any new light to guide us in solving problems that are still imperfectly understood. The papers are, of course, of unequal merit, and we propose briefly to call attention to a few only, selecting rather those the authors of which show themselves abreast of the difficulties to be overcome.

The Congress was the fourth of its kind, the two previous meetings having been held in Bordeaux, in the years 1886 and 1895, and the first in Brussels in 1880. The latest Congress, held in London, was organised by the Society of Arts—a society which has always shown a deep and very active interest in technical education. It occupied four days from June 15, when M. Leo Saignat and the Duke of Devonshire delivered short introductory addresses, till Friday, June 18, when it was brought to a close by a few words of thanks from the chairman, Sir Owen Tudor Burne, to those who had assisted.

It is not easy to correctly group the contributions under separate headings. Several papers were descriptive of the methods and conditions of education in the countries and districts with which the authors were familiar. Some few treated of educational problems, and these were perhaps of widest interest. The vexed question of the organisation of instruction and of examinations was very fully discussed; a whole morning was devoted to papers bearing upon the teaching of domestic science; and a special feature of the Congress was the prominence given to the subject of commercial education.

Among the papers dealing with educational method, those on the teaching of chemistry were certainly the most informing. The character of the chemical teaching best adapted to the requirements of persons actually engaged in industrial pursuits, and also to school children preparing for such pursuits, had recently been the subject of a thoughtful report, prepared by a Committee specially appointed by the Technical Education Board of the London County Council. This report had been widely circulated, and both Dr. Witt, of Berlin, and Dr. Lunge, of Zürich, referred to it in their communications to the Congress. It is doubtful, however, whether either of these professors fully appreciated the problem, as it presents itself to organisers of evening classes in this country. Neither in Germany nor in Switzerland is there anything approaching to the teaching of technological chemistry, by means of evening lectures, to artisans. When Dr. Witt states, in his paper on the "Relation existing between the teaching of pure chemistry and applied chemistry," that he "cannot admit any fundamental difference in the methods of research," every one will agree with him; but when he says, "we want no schools for producing specialists," it may be reasonably thought that his generalisation is too far-reaching. There are successful dyeing schools in all parts of Europe, and he, himself, admits that "Dyeing, calico-printing, and paper-making are . . . industries which may rightly claim the necessity of some special instruction in the methods of manipulation," even if no other industries have like claims. Although Dr. Lunge, who is essentially a technologist, puts in a plea for the study of applied chemistry, his views do not differ essentially from those of Dr. Witt. He is at one with other chemical teachers in recognising the importance of training in the methods of research for all students. He says very truly: "Nothing in these times of ours is likely to turn out a first-class chemist, worthy of being later on put in charge of a large factory, who has not tried his hand at original research." Dr. Lunge insists, however, on the advantages of specialised training, and refers to the demand of Dr. Böttinger, head of a chemical factory, having under him a staff of more than one hundred chemists, for the establishment of more professorships of technological chemistry. It is, nevertheless, clear that the difference between the training in pure and applied chemistry which Dr. Lunge has in mind, consists mainly in the addition to the curriculum of technological students of a course of instruction in engineering, in order that they may advance beyond the position, to use his own words, of "testing slaves," to understand something of the processes of manufacture on a commercial scale. Dr. Lunge shares with most German chemists the opinion, that the knowledge of chemistry and technology that can be imparted to adults in night classes is useless from the manufacturer's point of view. He says: "I do not even think that apart from isolated exceptions, such knowledge is of much good to the foreman, whose duty it is to carry out instructions, and to see that the men do their work as prescribed by the staff." And, more definitely, he tells us, that "in Germany, even in those factories where the work is carried on with the greatest chemical refinement, the foreman and ordinary workmen are neither required nor even desired to know anything of chemistry." Dr. Lunge, in this statement, is, of course, referring to large chemical works in which there is a complete system of division of labour and sectional work, and where every difficulty, as it occurs, is at once submitted to some member of the large staff of chemists employed. But it is now generally admitted that there are many small trades in which a knowledge of chemistry is useful to the ordinary workman, and that the training, even when it proceeds from the process to the principle, may be made educationally valuable in supplementing the still imperfect, and too brief discipline of the elementary school. Prof. Armstrong's characteristic paper, indirectly bearing upon this subject, entitled "Heuristic instruction in physical science," was intended to show that the aim of sound science teaching should be to put learners in the attitude of discoverers; and there is no doubt that if such teaching were more general, the necessity for specialised instruction would be lessened, and a great part of the technical teaching of evening students might be remodelled. Dr. Armstrong scarcely did justice, however, to the good work now carried on in some of the London polytechnic institutions, which do not, as a fact, give any undue prominence in their teaching to the requirements of the Science and Art Department's examinations. Every one, however, will agree with him, that in the organisation of education some machinery must be found, whereby those, in whom the control of education is vested, are brought into contact "with those who are actively engaged in improving the methods of teaching, *i.e.* in educational research."

---

[1] Report of Proceedings of the Fourth Meeting, held in London, June 1897.

Of the papers dealing more particularly with technical education in relation to trade subjects, that of Mr. Sidney Wells, on the qualification of teachers, will be read with most interest. He recommends the attachment to trade classes, of student-teachers who would be required to follow a course of instruction covering two or three years. The students would be selected from the members of separate trades, and would be remunerated by scholarships for the loss incurred during the period of their training. The means of providing a suitable training for trade teachers is a serious question that must be faced before long. In many of our trade classes, as now conducted, there is a lamentable waste of energy and money owing to the want of previous education of those who *faute de mieux* are appointed as instructors. A paper on "Theory and practice in trade teaching" deals with the same question from another point of view, showing the difficulties inherent in the teaching of trade subjects, as regards both the instruction to be given in the principles of science applicable to a particular trade, and the use of tools and machinery in workshop practice. In the discussion that followed the reading of these papers, and of others bearing incidentally upon the same subject, no serious attempt was made to grapple with the real difficulties of the problem. As might have been expected, there was considerable divergence of opinion as to whether technical instruction should be limited to the section of the trade in which the student is actually engaged, or should extend beyond it—a question which is unavoidably complicated by trades-union considerations. Mr. Steward, of the Central School of Arts and Crafts, in reference to the gold and silver trades, expressed his opposition to the system prevailing at the Vittoria Street School, Birmingham, where lads are encouraged to practise in the school other branches of the trade than the one at which they daily work. On the other hand, Prof. S. P. Thompson quoted with approval a passage from a report of the Technical Education Board to the effect, that at the Crafts School every effort was made "to give students a broader view and practice of the craft in which they are engaged"; and he exemplified his meaning by suggesting that silver chasers might be required to learn some other branch of the trade, such as engraving or enamelling. No fault can be found with many of the general principles enunciated in connection with trade teaching. That "all Technical Education Boards should negotiate with trade organisations with a view to co-operation"; that "technical education means a different thing in every trade or group of trades"; and that "all teachers of technical classes should be practical craftsmen," are propositions generally admitted. But, as regards teachers, we have already seen that the qualification of practical craftsmanship is not alone sufficient, and the difficulty arises in finding, united in the same person, the combination of qualities now needed.

No educational congress could be held in England without frequent reference to the subject of examinations. Questions of organisation and control, the influence examinations exercise, or might be made to exercise, on teaching, were very fully discussed. Prof. Wertheimer, speaking as a teacher, said: "There are not a few of us who would be prepared to make the establishment of a new examination a misdemeanour, unless the examination took the place of one or more already in existence." A few good suggestions were made in the course of the discussion for the better coordination of examining bodies, but progress in this direction can scarcely be looked for until the passing of a satisfactory bill for organising secondary education.

Mr. Quintin Hogg read an interesting paper on the new polytechnics of London, and Dr. Garnett referred in detail to the efforts made by the London County Council to place the instruction given in those schools on sound educational lines. The appointment of an educational principal to each school, the insistence on practical teaching in the laboratory or workshop, the encouragement of special advanced studies suitable to each locality, and the establishment of an efficient system of inspection, are evidence of the thought and care bestowed upon the direction of these institutions. They are still, however, in an experimental stage of existence; but in the provision they afford for secondary technical instruction, particularly of that kind adapted to evening students, they serve to indicate the great progress that has been made during the last five years.

Among the descriptive papers contributed by foreign delegates, that of Herr von Deifenbach, on the system of instruction in Würtemburg, would claim first consideration, if space permitted us to enter upon this group of subjects. None of these communications, however, add much to the information already furnished in the reports of various Commissions, and in the articles on foreign schools that have appeared from time to time in these pages, and in those of other journals.

The question of commercial education was fully discussed by several speakers, including M. Siegfried, Mr. Hewins, Mr. Sidney Webb, and Mr. Organ. The cry for commercial education, when carefully defined, seldom means more than a demand for the systematic teaching of modern subjects in our secondary schools. A course of French and German intelligently taught, lessons in scientific method illustrated by laboratory work in chemistry and physics, instruction in practical mathematics with graphic exercises, and lectures on history with explanations of the growth and routes of trade would satisfy most of the requirements of those who attach value to commercial education; and schools giving such a training will probably be found in every large town, when our secondary education is fairly organised. In connection with this subject, attention may be called to a report on commercial education in Europe recently issued from the Bureau at Washington. Dr. James, the writer of the report, tells us: "There is no institution in Great Britain, which fairly deserves the name of a commercial high school. . . . England is now beginning to wake up to the necessity of this sort of education. Boards of trade, teachers' conventions, educational societies, have all begun to agitate for its introduction." And, later on, he says: "Instead of taking hold of the subject at the right end, and organising a great institution in London, which might serve as a model for such schools elsewhere, the English began their work in this field, as in many similar instances, by establishing examinations." We feel the force of this criticism; but it is a question, to be carefully considered, whether high schools of commerce, similar to our science colleges, are really needed in this country, for the training of youths between the ages of eighteen and twenty-one in the details of office work. In their papers dealing with this question, Mr. Webb and Mr. Hewins have contributed to the better apprehension of the difficulties of the subject. As pointed out by one of these writers, the highest commercial instruction must be specialised to prove useful and attractive, and it should appeal to those engaged in the particular branch of commerce to which it refers.

We cannot close this short notice of the subjects considered at the Congress without reference to the papers on domestic economy. It must be admitted that the teaching of such subjects as cookery and laundry work has been made of late years distinctly more educative, and at the same time more practically useful. Much of this improvement is undoubtedly due to the educational experiments carried out by Mr. Hugh Gordon and by Mr. Heller, under the direction of the London School Board. The results of their work may be seen in the training schools attached to some of the polytechnics, and in the classes held in other institutions. Miss Walter's paper on "Domestic science as an element in girls' education" shows the great advance that has recently been made in the treatment of this important subject, and marks the distinction, not always clearly indicated, between the teaching of domestic science and of domestic arts. For persons qualified to give instruction in the science there is an increasing demand; and in her paper, Miss Walter gives an outline of the course of training such persons should undergo, and her suggestions do not err on the side of incompleteness.

It is doubtful whether the bulky volume, the contents of which we have endeavoured to summarise, will be read by many, even of those persons who are actually engaged in the work of technical education. Such congresses, however, serve a useful purpose in bringing people together for the interchange of opinion, and in inducing a few persons to think seriously on some of the difficulties which, owing to its wide meaning and the variety of its methods, the problems of technical education undoubtedly involve.

MICROSCOPIC STUDY OF ALLOYS.

THE study of metals with the microscope proceeds apace, and is now becoming as generally pursued among metallurgists as the determination of melting points has been during the last five years. Since the appearance of Prof. Roberts-Austen's article on "Micrographic Analysis" (NATURE, vol. lii. p. 367, 1895) of iron and steel, a large amount of work has been done; but most observers still devote themselves more or less exclusively to the study of this metal, attacking unsolved problems which seem to have great industrial importance. This tendency is unfortunate from some points of view, for the complex constitution met with in that protean element makes it less easy to explain the observed appearances until, by work on simpler alloys, a better acquaintance with the whole subject has been obtained. M. Charpy is one of those who has resisted the temptation offered by the alloys of industry, and in a recent paper[1] has given some interesting results of his investigations on binary alloys which are well worth re-statement.

It is now fairly established that microscopic examination gives an immediate analysis of alloys, which is all the more valuable for differing in its results from chemical analysis, since these differences indicate the existence of definite compounds, and elucidate the structure in other ways. The immediate analysis is now made with the aid of a planimeter, as Sauveur recommended, by which the ratio of the areas occupied in the microscopic field by the various constituents can be measured. The metal or metals forming each of these constituents can often be indicated by their colour, hardness and, above all, the effects on them of various reagents, and thus a full account of the alloy can be given.

In the normal type of constitution of binary alloys, crystals of one of the metals, or of a definite compound of the two, are seen enveloped in a second constituent, which is generally the eutectic alloy, containing both elements in a very finely-divided state. The composition of the eutectic mixture remains constant, whilst the amount of isolated crystals varies with the percentage composition of the alloy. The limiting cases of a pure definite compound or metal, and of a pure eutectic mixture may be grouped with these alloys.

Eutectic alloys vary in appearance according as they have been cooled slowly or quickly. In the latter case, the surface is uniformly striated, but the crystals or crystallites are so small, that it is difficult to obtain satisfactory photographs of them. When the solidification is slow, however, the separation into lamellæ is strongly marked, especially when viewed under high powers, and this structure is highly characteristic of eutectic alloys, being easily traced in any of them whatever the metals in the alloy may be. It is well shown in Fig. 1, which represents an alloy containing silver 66 per cent., antimony 34 per cent., magnified 500 times; the metal has been treated with sulphuretted hydrogen, which has blackened the silver and left the antimony unchanged.

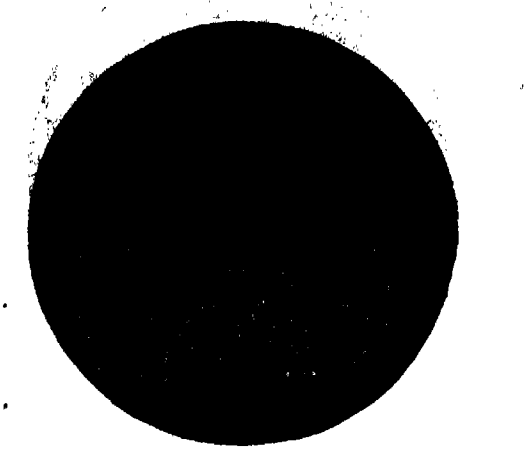

FIG. 1.—Alloy of silver, 66 per cent.; antimony, 34 per cent.

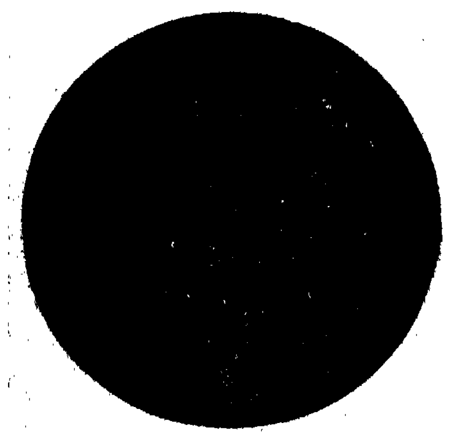

FIG. 2.—Alloy of tin, 90 per cent.; antimony, 10 per cent.

In the same figure some straight edges can be seen, in which the ramifications end, and which sketch out shapes resembling those of crystals of antimony. The presence of these crystallites or incipient crystals in eutectics constitutes one of the resemblances between them and the micro-felsitic basis observed in many igneous rocks, and it seems likely enough that if light transmitted through these alloys could be examined, it would show that they are on the borderland between crystalline and amorphous matter.

---

[1] "Étude Microscopique des Alliages Métalliques. *Bull. de la Soc. d'Encouragement*, vol. ii. (1897), p. 384.

Besides the normal type of binary alloys, in which eutectics are observable, there is a second type consisting of alloys of metals which form isomorphous mixtures with each other. These alloys, whatever may be their composition, consist of only one species of crystals, which fill the whole space, the composition and the properties of the alloys usually varying in a continuous manner in each crystal. The number of metals capable of forming isomorphous mixtures with each other is small, the bismuth-antimony alloys being the only ones out of fourteen series investigated by M. Charpy in which this property was found to exist, but, on the other hand, there are many cases of definite compounds of two metals isomorphous with one of them. Thus, for example, microscopic study has enabled M. Charpy to detect a compound of tin and antimony containing about 50 per cent. of tin and isomorphous with antimony, although the freezing-point curve, worked out by Roland-Gosselin, and consisting of three branches having their concavities upwards, and meeting in two angular points or maxima, gives no direct indication of the relation between these metals.

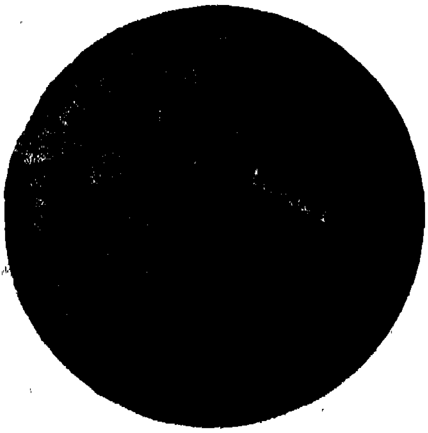

FIG. 3.—Alloy of tin, 75 per cent.; antimony, 25 per cent.

FIG. 4.—Pure gold. × 1000 diameters.

In Fig. 2, in which the alloy containing 10 per cent. of antimony is shown, the cubical crystals appear to consist of the 50 per cent. alloy set in a eutectic magma. Fig. 3 shows the alloy with 25 per cent. of antimony. As the proportion of antimony in the whole mass approaches 50 per cent., these crystals invade the whole field, and numerous minute cracks appear, on the edges of which is seen a secondary crystallisation without the interposition of an intermediate substance. This structure is characteristic of a pure or homogeneous substance, as in the beautiful micro-sections of pure gold prepared by Osmond and Roberts-Austen,[1] one of which is reproduced in Fig. 4. When the proportion of antimony is increased above 50 per cent. a eutectic magma shows no signs of reappearing. Similarly in the tin-antimony series, there is evidence of a compound containing 20 per cent. of antimony and isomorphous with silver, and in the silver-tin series a compound containing 30 per cent. of tin also appears to be isomorphous with silver. An investigation of the triple alloys of these metals would be interesting, as probably affording fresh examples of isomorphous series.

T. K. R.

NOTES.

THE Municipal Council of Paris has made a grant of three thousand francs to the fund for the erection of a statue of Lavoisier in Paris.

M. MOUREAU has found in the records obtained at the Parc-St.-Maur Magnetic Observatory, a distinct disturbance evidently produced by the Indian earthquake of June 12. The exact time of the magnetic perturbation registered on that day is 11.37 a.m.

AT a recent meeting of the Durham and Northumberland Archæological Society it was unanimously resolved to obtain a portrait of the president, the Rev. W. Greenwell, F.R.S., Canon of Durham, to be placed in the Cathedral Library, Durham. A strong committee has been formed to further this object, and more than one hundred guineas have already been paid or promised. Further subscriptions are invited, and will be received by Mr. C. Rowlandson, at Messrs. Hodgkin's Bank, Durham, or by Mr. J. G. Gradon, Lynton House, Durham.

SIR RUTHERFORD ALCOCK, formerly president of the Royal Geographical Society, died on Tuesday, at the age of eighty-eight. The death is also announced of Prof. C. E. Colby, professor of organic chemistry in Columbia University.

DR. G. H. OTTO VOLGER, who died at Sulzbach, in the Taunus, on October 18, aged seventy-five, was at one time a notable figure in scientific and political circles in Frankfurt. A many-sided man, he contributed during his life a number of miscellaneous papers to various natural history and philosophical societies. He made several original contributions to geology, and wrote on the origin of springs, and on meteorological and mineralogical topics. During the time of his greatest activity, while resident in Frankfurt, he founded a society for the cultivation of sciences and arts called the "Freies deutsches Hochstift." Nearly forty years ago, when the old residence in the Hirschgraben, where Goethe was born, came into the market, he bought it. For a time he lived in it, with the direct object of gradually restoring it, room by room, to the state in which it existed (as described partly in *Dichtung und Wahrheit*, and partly in *Wilhelm Meister*) during the boyhood of the poet. This done, he made over the Goethe-house to the Hochstift, of which he was then, and for twenty-two years, the president.

---

[1] Osmond and Roberts-Austen, "On the Structure of Metals, its Origin and Changes," *Phil. Trans.*, vol. clxxxvii. (1896), A., pp. 417–432.

After Frankfurt had ceased to be a free city, and imperial ideas swept over the old place, Dr. Volger found himself increasingly out of harmony with the new *régime*, and he withdrew from Frankfurt, first to Soden and lately to Sulzbach. In accordance with his express wish, his funeral at Frankfurt, on the 20th ult., was strictly private.

We have received the Year-book of the Cambridge Philosophical Society, containing the addresses of the Fellows of the Society, and a list of the English and Foreign Societies with whom the publications of the Society are exchanged. It would appear that the Society is a convenient meeting-ground for Cambridge men engaged in scientific work. Papers for presentation to the Society are received by the Secretaries at the library of the Cambridge Philosophical Society, Cambridge. The Proceedings are published three times yearly—the publication of the Transactions is to be accelerated: the meetings are held every fortnight during full term. The following is a list of the new honorary members, elected May 24, 1897:—Major Macmahon, R.A., Prof. Charles A. Young (Princeton), Prof. Michelson (Chicago), Dr. Boltzmann (Vienna), Prof. Righi (Bologna), Prof. Mendeléeff (St. Petersburg), Sir Archibald Geikie, Prof. Dana (New Haven, Conn), Sir John Kirk, Prince of Monaco, Rev. Canon Norman (Durham), Prof. Wilhelm Pfeffer (Leipzig).

An instructive fisheries exhibition, arranged to illustrate the fishing industries and the application of science to agriculture, was opened in the Zoological Museum of the University College, Liverpool, on Friday last. The exhibits are fully described in a guide to the exhibition published by the authorities. There is a series of the food fishes of this district, with the more important food matters of each; also a series of useful and useless fishes which compete with one another by eating the same food. Another exhibit contains specimens of the shell-fish of the district, showing stages in the life-history and growth, legal and illegal sizes, pearl formations, and pearls. A case is devoted to a display of printed matter, plates, photographs, drawings, and lantern slides, illustrating the publications, both administrative and scientific, of the Lancashire Sea Fisheries Committee, and other work bearing upon the fisheries of the district. The drawings and sketches include a number made by Prof. Herdman in illustration of his joint investigation with Prof. Boyce on the diseases of oysters and the connection between the oyster and disease. The exhibition will no doubt promote a more widespread interest upon the important question of sea-fishing, and thus assist in increasing the harvest of the sea. As Prof. Herdman pointed out at the opening ceremony of the exhibition, fishes are animals, their food is composed of animals, and their enemies are animals. In all the operations of their life, their feeding and breeding, and so on, they are subject to the same biological laws which regulate the lives of all animals in the sea. The investigation of fishery questions is applied biology, and if our fisheries are to be benefited they must be treated in a scientific manner. We do not trust to unaided nature for our supplies of bread-stuffs and beef. Why then should we trust to nature for fish? As there is an agriculture of the land, so there must be an aquiculture of the sea. Fishermen must in the future be farmers of the sea-shore, not hunters as they have been in the past.

Sir J. Wolfe Barry, in an address at the opening of the new session of the Institution of Civil Engineers on Tuesday, said that the Institution now numbers on its roll 7075 persons. Reviewing the subject of the examinations recently instituted, he pointed out that they are intended to show that candidates for election into the class of Associate Members are acquainted with those general principles which have always been and must be recognised as the basis of the engineering profession, and also to make clear that each candidate possesses a somewhat fuller scientific knowledge of the elements of the particular branch in which his special training has lain. Practical knowledge is no less necessary now than formerly; for the examinations have not been instituted in lieu of other qualifications set out in the by-laws, but in addition to and supplementary of them.

We have received the Report on the Administration of the Meteorological Department of the Government of India in 1896-97. It is divided into two parts; the first gives a general account of the results during the past year, and the second gives details of administration, chiefly in the form of tables. In the branch of marine meteorology two clerks have been regularly engaged in collecting data from ships visiting Calcutta and Bombay, and more than two thousand logs have been extracted. The observations are tabulated day by day, and are utilised in the preparation of charts of the Monsoon area. Observations have been made for some years past in certain forest areas with reference to the influence of forest-growth upon the distribution of rainfall, but have now been discontinued. Photogrammetric cloud observations have been regularly made since March last at Calcutta and Allahabad with the best type of instruments, which were constructed in Paris. Storm warnings are issued when necessary, partly from Calcutta and partly from Simla, and timely notice appears to have been given of all the more important disturbances. Among the various useful publications, we may mention the printing of the hourly observations formerly made at Trevandrum, under the superintendence of the late J. Allan Broun. The work of publication of the hourly values is now completed, and Mr. Eliot has undertaken their discussion, from which we anticipate some valuable results. He hopes to complete it during the present year.

A recent number of the Cape of Good Hope *Agricultural Journal* contains an important report on rinderpest by three Russian investigators, M. Nencki, N. Sieber, and W. Wyznikiewicz. These gentlemen were appointed by the Russian Government two years ago, to study how far sheep of the Merino family are subject to rinderpest, and at the same time to investigate the nature of the contagium of this disease. Their inquiries were carried on first in the Kuban-Cossack country, and later at the Institute for experimental medicine in St. Petersburg. They claim to have discovered the genuine contagium of rinderpest, which does not belong to the bacterial class of germs, but appears to partake more of the character of the amœba. After experimenting with about a hundred different media, in the hope of separating out the specific rinderpest agent, their efforts were rewarded by the discovery of "slightly luminous bodies in size from 1–3 μ, mostly round, a few being oval, pear-shaped, or drawn to a point. On the larger ones swellings may be seen, and, in a few, a grain lying in the centre. The larger and duller individuals show amœboid developments; some also have one, seldom two, ciliated protrusions." With fresh cultures of these organisms the rinderpest can be generated. Such cultures, however, are very perishable, and it is recommended to re-inoculate the culture daily. The best material for the cultivation of these organisms is apparently that which is rich in animal mucus, and by employing solutions containing an abundance of mucine, the authors succeeded in at length obtaining them in a living condition outside the animal's body. Great difficulty was experienced in ensuring the virulence of rinderpest cultures, but this trouble has to a considerable extent been overcome. "All organs and juices of diseased animals contain the rinderpest germ," the authors assert; and now that their methods have been brought before the scientific world, it only remains for other investigators to repeat and, we trust, confirm the important results which have been obtained.

THE first number (November) of the new volume of the *Century Magazine* contains several contributions of scientific interest. Prof. H. F. Osborn writes an appreciative notice (accompanied by a portrait) of the late Prof. Cope. Shortly before his death Prof. Cope communicated to Mr. W. H. Ballou a number of interesting views which he held as the result of many years' study of the skeletons of Saurians, or lizard-like reptiles, found in various beds of the Rocky Mountains and other regions of the United States. He had arrived at some original and ingenious speculations with regard to the structures and habits of these animals, and, in addition, he completed the evolution of the carnivorous line of Saurians. Mr. Ballou now presents these views in an interesting article containing several vigorous illustrations, in which Mr. Knight well conveys Prof. Cope's impressions of how ancient Saurians lived and moved.—Mr. Jonas Stadling, who witnessed the start of Herr Andrée's balloon expedition towards the north pole, contributes to the *Century* a short description of the preliminary arrangements, accompanied by several reproductions of photographs of the balloon when beginning its journey. Mr. Stadling states that the balloon lost about fifty cubic metres of gas every twenty-four hours when it was standing filled in the balloon-house, from which rate of escape of gas it is concluded that the balloon would float about thirty days.—Accompanying an article upon Mrs. Cameron and her photographs, in the *Century*, is a fine reproduction of her successful portrait of Sir John Herschel.

THE continually increasing difficulty of dealing with the sewage of large towns lends an interest to any scheme which appears to give satisfactory results in the purification of the effluent from the sewers so as to render it fit to flow into the rivers without polluting the water, and creating a nuisance. So great is the difficulty and cost of purifying the sewage up to the required standard, that Manchester has been advised that the only practicable way of disposing of the effluent from the sewage tanks, which now flows into and pollutes the Ship Canal, is by constructing a culvert fifteen miles long for the purpose of conveying it to the estuary of the Mersey at a cost of 258,000*l.*, and it is intended to apply to Parliament in the ensuing session for the necessary power to carry this work out. The sludge from the tanks is to be taken out to sea. The County Council of London employ a fleet of six steamers which are regularly engaged in conveying the sludge deposited in the outfall tanks at Barking and Crossness a distance of fifty miles to Barrow Deeps at an annual cost of 32,000*l.*; the material so removed amounting to over two million tons a year. At Exeter a new system of "septic" treatment has been tried, and it is described by Mr. Cameron, the City Surveyor, in a paper read before the Devon and Exeter Architectural Society. It is claimed for this system that the sewage treated by this process in the tanks is brought under the influence of micro-organisms; the decomposition of the matters which would otherwise undergo putrefaction being effected by the presence of these micro-organisms, their products being ammonia and carbonic acid with some other gases. The bottom of the tanks after six months' use, when exposed, showed only a thin layer of black earthy matter, together with mud and grit. The effluent is not offensive, and it is stated that it does not ferment. At Wolverhampton recent experiments have shown that filtering the sewage through coal-dust is an effectual way of purifying it, and that a very satisfactory effluent can be obtained by passing 200 gallons of sewage through one square yard of filtering material in twenty-four hours.

THE interest of the many recent observations of earthquake-pulsations has led Dr. M. Baratta, who is preparing a history of seismology, to search for early accounts of these phenomena in various scientific works. He has succeeded in discovering several forgotten records, which are described in a paper in the *Rivista Geografica Italiana* (1897, fasc. viii.). Those of pulsations observed with magnetic apparatus date back to 1681, with astronomical instruments to 1767, and with levels to 1833. Dr. Baratta's examples are taken from French and Italian sources; and it can hardly be doubted that others, equally interesting, would be obtained from an examination of English and German works.

IN an interesting and well-illustrated little memoir on "L'Echelle réduite des expériences géologiques," in the *Revue de l'Université de Bruxelles*, M. W. Prinz sets himself to answer the question whether experiments conducted to explain geological phenomena become untrustworthy on account of the small scale and different materials with which they are necessarily performed. His answer is decisively negative. The results of experiments like those of Cadell on the production of planes of major and minor thrust are exactly similar to those produced in the planing of steel, the difference in scale between the two classes of experiments being greater than that between Cadell's thrusts and those of the Highlands which they were intended to explain. With regard to difference of material results similar to those of Daubrée on plate-glass may be reproduced in mastic, cast-iron, modelling clay, and half-solid mortar; in all cases cracks similar to the joints and cleavage in rocks are produced. Again, the differential movement which makes marginal crevasses in glaciers may be imitated in the cutting of glass by a wheel, by drawing a needle over dry plaster, by a pencil on paper, by footsteps, or by dragging a cane over thick snow, and even by moving a cart-wheel over a muddy road. Further instances, including the action of a diamond on glass, and a bibliography, conclude this interesting memoir.

MR. ALBERT F. WOODS, of the Division of Vegetable Physiology and Pathology, United States Department of Agriculture, describes in the *Botanical Gazette* a novel method of preserving the green colour of plants for exhibition purposes. The principle involved is to bring about a combination of the chlorophyll in the cells of the plant with copper. The resulting compound, copper phyllocyanate, is practically insoluble in any of the ordinary preserving media except strong alcohol, and is not destroyed by light. The resulting green can scarcely be distinguished from the normal chlorophyll green. The process described is a somewhat complicated one. After removing the air as completely as possible from the surface and from the intercellular spaces by immersion in 90-95 per cent. alcohol, or by means of the air-pump, the tissues are placed in a 5 per cent. solution of glycerol containing enough dissolved copper sulphate or copper acetate to give it a bluish tint. The uncombined copper is dissolved out by a dilute glycerin-formalin solution, and the object may be preserved in this solution or in any of the usual media except strong alcohol.

THE number of printed specifications of patents in the Patent Office Library at the present time is well over a quarter of a million. To search through these specifications in order to obtain information as to the novelty of an invention is thus a tremendous task even for the trained expert; yet by omitting such a search many a patentee has found, after paying his fees, that his patent was worthless, because it had been anticipated; for the Patent Laws of this country make no provision for an official search as regards novelty, and all patents are taken out at the risk of the inventors. The searcher is, however, greatly assisted in his task by a series of indexes and abridgments published by the Patent Office as a guide to the specifications themselves, and freely distributed to the principal public libraries in this country. The abridgments give a general description of the nature of every invention patented, and the object of their publication is to enable the would-be patentee to carry out, at any rate in some cases, what may be termed a fireside search. The volume containing abridgments of patents belonging to the class of *Philosophical Instruments*, and referring to the years 1884–88, has been sent to us by the Comptroller-General of Patents. In it we find concise descriptions (usually illustrated by diagrams) of optical, nautical, surveying, mathematical, and meteorological instruments and accessories. Some of the subjects of the patents are very trivial, while others are most ingenious; so an examination of the whole will be found amusing as well as instructive. The favourite scientific instruments upon which human ingenuity exercises its powers seem to be barometers, clinometers and other instruments for measuring vertical angles, magnetic compasses, hygrometers and hygroscopes, lenses, levels and plumbing instruments, logs and leeway indicators, magic-lanterns and other projecting apparatus, mathematical drawing instruments, microscopes, reflectors, protractors, sounding apparatus, spectacles and eye-glasses, surveying instruments, telemeters, thermometers and pyrometers, and stands for cameras and telescopes. The volume thus provides the material for a liberal education in the construction of scientific apparatus, in addition to which it is full of interest to every one with an inventive turn of mind.

IN the current number of the "Annotationes Zoologicæ Japonenses" Mr. Nishikawa describes a newly-discovered mode by which the eye of the lower side of a flatfish travels round to the upper side during metamorphosis. Agassiz observed that in the majority of flatfishes the eye of the (eventually) blind side travels round the dorsal edge of the head until it attains its final position, and that not until this rotation is completed does the dorsal fin grow forwards beyond the level of the eyes. In *Plagusia*, on the other hand, the dorsal fin is known to grow forwards to the snout while the eyes are still symmetrical, and the right eye attains its final position on the left side of the fin by penetrating, in the course of its rotation, through the soft tissues at the base of the fin. In the fish observed by Mr. Nishikawa the dorsal fin also grows forward before the rotation of the right eye, but this anterior extension does not unite with the head until after the rotation is completed. Its ventral margin is contiguous with the dorsal surface of the head except posteriorly where there is a distinct hole, bounded by the head and the anterior extension of the fin, for the passage of the right eye, which thus travels round the dorsal side of the head without sinking into its tissues. It is clear, as Mr. Nishikawa points out, that the mode by which the change of position is effected in this fish is intermediate between that observed in ordinary flatfishes, which are destitute of an anterior extension of the dorsal fin at the time of transformation, and that which is exhibited by *Arnoglossus* and *Plagusia*, in which types the anterior extension of the fin coalesces with the head before rotation of the eye, and requires to be perforated for the passage of that organ. The genus of the Japanese fish could not be ascertained with certainty, but it is believed to be closely related to the genus *Plagusia*.

THE forty-third annual report dealing with the work of the Australian Museum, Sydney, during the year 1896, has just come to hand. The most important presentations to the Museum during the year was the Dobroyde collection of Australian birds and eggs, containing several thousand skins and eggs—the result of forty years collecting. This was purchased by the Government of New South Wales from Mr. J. S. Ramsay, and transferred to the custody of the Trustees of the Museum. Another valuable donation is a mass of meteoric iron weighing just over 44 lb., found on the Nocoleche Holding, near Wanaaring, New South Wales, and presented to the Museum by Mr. G. J. Raffel. The semi-fossil remains of a Dugong, discovered in the excavations for a canal, near Sydney, have also been presented to the Museum. This is the first instance of the discovery of Dugong remains so far south. Among other noteworthy acquisitions are: The bower or playground of Newton's Bower-bird (*Prionodura newtoniana*), types of the Honey-ants of the Horn Central Australian Exploring Expedition, and a further collection of bird skins from the same, some ancient Peruvian urns, a collection of Australian Coleoptera, and the remains of the Asiatic elephant Jumbo. Mr. Charles Hedley, one of the officers of the Museum, who was permitted to accompany the Royal Society's Coral Reef Boring Expedition, succeeded in amassing an interesting collection during his stay on Funafuti, particularly of invertebrate and ethnological subjects. The collections are now in process of description by the scientific staff of the Museum. A commencement has been made at the works for extension of the Museum buildings, for which a sum of 6000*l.* was voted by the New South Wales Parliament in 1895. The old ant-eaten roof has been removed, and a new roof, built of steel, wood and copper, has been constructed. While this was in progress a thorough inspection of the building was made to ascertain the extent of the ravages of the "white ant," with the result that further depredations were discovered. These terrible termites were found to have penetrated under the floor of the ethnological hall, and completely destroyed the woodwork of that structure as of the roof. It is not surprising to read that discoveries of this kind gave the curator, Mr. R. Etheridge, jun., plenty of cause for anxiety during last year. The chief change in the staff of the Museum is the appointment of Mr. W. J. Rainbow to succeed the late Mr. F. A. A. Skuse as officer in charge of the entomological collections.

THE difficulty of the problems which await the investigator into the chemistry of the enzymes is well illustrated by the results, published in the current *Berichte*, of an attempt made by A. Wroblewski to isolate diastase. The greater part of the substance usually known as diastase was found to be a carbohydrate, which yielded arabinose when boiled with acids. The active constituent, on the other hand, was found to have all the properties of a protein, although the author could not be sure that he had prepared it in an absolutely pure state. The proteid nature of the enzyme follows from the facts that the residue left after removing the inactive carbohydrate shows all the characteristics of a proteid body, and at the same time exerts the diastatic action on starch. This research affords, for the first time, a definite experimental basis for the enrolment of this enzyme among the proteids, although many investigators had taken this view of its nature on general grounds.

THE *Bulletin* of the Bussey Institution, vol. ii. part 6, published under the authority of Harvard University, consists of a paper by Prof. F. H. Storer, on some of the chemical substances in the trunks of trees, which serves to show that other substances besides starch are stored up in large quantities as reserve food-material in the winter, to be converted into sugars in the spring.

THE additions to the Zoological Society's Gardens during the past week include a White-crested Tiger Bittern (*Tigriosoma leucolophum*) from West Africa, presented by Dr. J. F. Dell; an Alligator (*Alligator mississippiensis*) from Southern North America, presented by Mr. J. H. Renals; a Common Chamæleon (*Chamæleon vulgaris*) from North Africa, presented by Mr. G. E. Gratton; two Great-billed Rhea (*Rhea macrorhyncha*) from North-east Brazil; a Pennant's Parrakeet (*Platycercus pennanti*) from Australia, deposited; six Common Rhea (*Rhea americana*), bred in Holland; a Many-coloured Parrakeet (*Psephotus multicolor*) from Australia, purchased; a Sambur Deer (*Cervus aristotelis*, ♀), a Hog Deer (*Cervus porcinus*, ♀) from India, received in exchange; three Shaw's Gerbilles (*Gerbillus shawi*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

The Photography of Faint Moving Celestial Objects.—An ingenious but simple method of photographing unseen or very faint moving but known celestial objects has recently been suggested by Prof. Barnard (*Astr. Nachr.* No. 3453). Every one knows that in order to photograph a faint celestial object, it is only necessary to prolong the exposure until a sufficiently burnt-out image is recorded on the photographic plate. If, however, the object has a rapid motion, then the image will not remain on one part of the plate a sufficiently long time to record its impression, since the clockwork of the instrument is regulated to counterbalance the apparent motion of the stars. Prof. Barnard's idea is to use, in the eyepiece of the guiding telescope for following the object in question, two guiding cross wires attached to a light frame which can be moved by a delicate clockwork (the works of an ordinary watch are sufficient), the speed of which can be regulated to the motion of the object. Arrangements can also be made that its direction of motion can be regulated to any position-angle. When adjusted to the eye end of the guiding telescope, the instrument is set so that the amount and direction of motion of the cross wires shall coincide with that of the comet or minor planet.

A star in the field of view is then bisected by the cross wires, and the mechanism set in operation, the star being kept bisected by the ordinary slow motions for star guiding. It will thus be seen that although the operation is exactly the same as if the star itself were being photographed, it is the image of the comet which will remain stationary as regards the photographic plate, while the stars will produce trails. Prof. Barnard mentions that the device will be very serviceable for photographing visible comets with ill-defined nuclei, as these have no definite points to guide by, and it is for this work that he is going to have an instrument of this kind made.

Sunspots and the Weather.—Although nearly every one is agreed that sunspots do influence our weather, the relation between them is evidently not a very simple one. Statistics of the weather from places situated in moderate latitudes do not, at any rate, bring out very clearly direct indications of such a connection; but when they are gathered from a large region near the equator, such as India, then the effect of the sunspot cycle on the weather is more decisive. The first effects of solar disturbances would be felt at the equator, and as the mean temperature does not vary very much from the extremes, a general small increase or decrease would make itself apparent. In more northern latitudes local disturbances seem to tend to a great extent to mask the effects of a variation in the amount of solar radiation.

Mr. Alexander MacDowall has, however, examined a number of weather statistics from several European stations—viz. Bremen, Paris, Geneva, Greenwich—and he finds that they are suggestive of a relation to the sunspot cycle (*Quarterly Journal of the Royal Meteorological Society*, vol. xxiii. No. 103).

In making out his curves he says he has used smoothing methods freely, sometimes smoothing with averages of five and sometimes with additions of five. In this investigation the author has compared corresponding portions of successive years, such as the winter half, summer half, the four seasons, &c. To sum up the inquiry in his own words, he says: "In the climate of Western Europe there is apparently a tendency to greater heat in the summer half and to greater cold in the winter half near the phases of minimum sunspots than near the phases of maximum; the contrast between the cold and heat of the year thus tending to be intensified about the time of minimum sunspots. . . . If we accept the view to which direct observation of the sun seems to lead, that solar radiation of heat is greater about the time of maximum sunspots, we appear to have a direct explanation why, on the one hand, our winter cold should thus be moderated; and as to the contrary effect in the summer half, it is not difficult to conceive that solar activity may, by increased evaporation, bring about the presence of more cloud, and so give us cool, rather than hot, summers."

The conclusions drawn by Mr. MacDowall are exactly what would be expected, and they corroborate those that were formed many years ago. Thus, for instance, in a pamphlet published in 1879, and submitted to the Indian Famine Commission, we read: "For it is an acknowledged and readily accountable fact that presence of cloud in the summer is associated with coolness, and in the winter with warmth; and in like manner that a clear sky, which in the summer, by promoting solar radiation, favours the development of great heat, in the winter, by giving free scope to terrestrial radiation (in the then comparative absence of solar radiation), tends to produce excessive cold. The fact, therefore, that clouds are more prevalent in the *summers* of maximum sunspot years, and in the *winters* of minimum sunspot years, is only another way of saying that both summer and winter are *cooler* at the former epoch and *warmer* at the latter."

Comet Perrine, October 16.—The following is a continuation of the ephemeris of this comet, computed by Herr. J. Möller (*Astr. Nachr.*, No. 3454) from the observations of October 16, Mount Hamilton; October 18, Strassburg, and October 20, Hamburg (two observations).

The following comments relate to the appearance of this comet:—

Karl Mysz: 6-inch refractor in Pola. October 18, comet 10 mag.; axis of tail, 200°; nucleus appears sometimes double or oblong. October 19, same appearance and brightness as yesterday; nebulosity has diameter of 5′.

J. Möller: 8-inch refractor in Kiel. October 20, nucleus 10·3 mag., oblong and hazy; fan-shaped tail of about 2′ in length, having a position angle of 200°.

Schorr and Ludendorff: Hamburg refractor. October 20, comet has faint nucleus, 10·5 mag.; tail, 0′·5 towards south. October 24, fainter than October 20; no distinct nucleus.

Picart: at Bordeaux, October 20. The comet has a very feeble tail; its general form is that of an elliptical nebula.

The Director of the Lick Observatory.—We regret to read in the *Astronomische Nachrichten* (No. 3454) that, after a continuous connection with the Lick Observatory for twenty-three years, and a service at Mount Hamilton since the year 1888, Prof. Holden has resigned his post, and will terminate his official relations with the Observatory December 31, 1897. His address after October 1 will be Smithsonian Institution, Washington.

RELATION BETWEEN INDIVIDUAL AND RACIAL VARIABILITY.[1]

MR. BREWSTER'S memoir refers to "allied races" without defining that phrase, but apparently basing it on the idea of divergent races sprung from a common source. The mean (or typical) characters of these races differing from one another, as individuals of the same race differ among themselves, two systems of variables exist in respect to each and every character: (1) a single system, referring to the means of the different races; (2) several separate systems, referring alike to the individual values of the same character; in each and every race. He supposes the ordinary law of frequency to be approximately applicable to both systems, so that the peculiarities of every series admit of being roughly expressed by its own mean and quartile (= probable error). In order to reduce the variability of each series to a common scale, he works, not with the observed quartiles, but with what may be called *reduced quartiles*, namely the indices formed by dividing each quartile by its corresponding mean. These being comparable on equal terms, are his "measures of variability."

The first and more important part of the memoir deals with eighteen different characters in eight human races, the data being derived from Weisbach's *Körpermessungen*. The number of individuals in each of the selected races is unfortunately very small, ranging from eight to twenty-six, though he is able to utilise twenty races for obtaining the common racial mean. His method of discussion is based on the safe ground that, if racial variability be associated with individual variability, whenever any specified character is more variable than another specified character in the one, it will (on the whole) be more variable in the other also. Therefore if the reduced quartiles of the two characters, in the series of means of races, be called A and B, and those in that of the individuals of any given race be called *a* and *b*, then if A be greater than *a*, B would (on the whole) be greater than *b*, and conversely. More briefly and fully, if the *signs* of the differences (A-B) and (*a*-*b*) are alike, the evidence, so far as it goes, favours the suggested idea of a connection between racial and individual variability; if the signs are different it discountenances it.

---

[1] "A Measure of Variability and the relation of Individual Variations to Specific Differences." By Edwin Tenney Brewster. (*Proc. Amer. Acad. Arts and Sciences*, May 1897.)

The test is rough, but is of value when applied on a considerable scale with concurrent results, as in the present instance. The eighteen characters admit of $\frac{1}{2}(18 \times 17) = 153$ different pairs of combinations of the form (*a*-*b*), in each of the eight races; that is 1224 pairs in all. Each of these has been compared with its associated pair in the series of means of races, of which there are altogether $\frac{1}{2}(8 \times 7) = 28$. The result is that in seven out of the eight races the cases testifying to the existence of the suggested association are from twice to thrice as numerous as the others, and in the eighth race they are 1½ times as numerous. Nay more, there is some evidence that the most variable characters in the one, are the most variable in the other. This conclusion is corroborated by three other inquiries of the same kind, two into rodents and one into carnivoræ. The error introduced by the strained assumption, that the ordinary law of frequency holds good for the series of means of allied races, does not seem likely to invalidate the general conclusion to a serious extent. It therefore appears that Mr. Brewster has provisionally established his thesis that whenever any specified character varies much in individuals of the same race, it is probable that it will be found to vary much in "allied" races, and conversely.

ON THE CONSTITUTION OF THE ELECTRIC SPARK.[1]

IF a Leyden jar is discharged through metal electrodes, and the spectrum of the spark is examined, it is found that the metallic lines are not confined to the immediate neighbourhood of the poles, but are seen sometimes in the centre of the spark, several millimetres away from the electrodes, from which they must have been projected with considerable velocity.

It has always seemed to me to be a problem of interest, to measure the velocity of projection. A knowledge of it may teach us something concerning the mechanism of electric sparks and, in addition, we may hope to obtain information on some important points in spectrum analysis, which are at present under discussion. Thus, for instance, if the speed with which a molecule is pushed forward into the centre of the spark depends on molecular weight, we may separate from each other those lines of the spectrum which belong to different molecular combinations. For many years past I had made various unsuccessful attempts to deal with this problem, when I became acquainted with the elegant method, used by Prof. Dixon in some of his recent experiments, in which a photograph is taken on a film fixed to the rim of a rapidly revolving wheel, of which the speed may easily be made sufficiently large to measure velocities of moving luminous particles up to 2000 $\frac{\text{metres}}{\text{second}}$. This number might be doubled or trebled with improved appliances.

The experiments were conducted by Mr. Gustav Hemsalech, to whose care and skill their success is largely due. Without entering into a detailed description of the apparatus, it will be sufficient to say that the photographs, which I now submit to the Section, were taken on a film moving with a linear speed of about 80 $\frac{\text{metres}}{\text{second}}$ in a direction at right angles to the slit of the spectroscope. The lines of the metal appear inclined instead of straight, in consequence of the finite velocity of the luminous molecules. The air lines, on the other hand, though slightly broadened, remain straight. The sparks were taken from five large Leyden jars, charged by means of a Voss machine. Each single spark produces a good spectrum, reaching approximately from $\lambda = 5000$ to $\lambda = 4000$.

One of the photographs, in which zinc poles were used, shows that the velocity of the molecules is gradually diminishing as they move away from the pole. Close to it the speed seems very great, the average velocity up to a distance of about one millimetre being about 2000 metres per second. At a distance of four millimetres the speed is reduced to something like 400.

In another experiment one pole was zinc, while the other was bismuth. Some bismuth lines are found to be decidedly more curved than those of zinc, indicating a smaller velocity. But the line of bismuth, which lies at 4560, seems almost straight.

When the poles are moistened with a solution of calcium chloride interesting results are obtained, the calcium line at 4226 being more inclined than H and K.

The experiments were made with comparatively rough appliances, but a more perfect apparatus is in course of construction; and the author hopes to continue the research in conjunction with Mr. Hemsalech.

---

[1] By Prof. Arthur Schuster, F.R.S. (Read before Section A of the British Association at the Toronto meeting.)

PHYSIOLOGY AT THE BRITISH ASSOCIATION.

THE section of Physiology at the British Association meeting at Toronto was a large and active one. Under the presidency of Prof. Michael Foster a large body of physiologists attended in about equal numbers from the east and west of the Atlantic. Meetings were held on the Thursday and Friday, August 19 and 20, and on the Monday, Tuesday and Wednesday, August 23, 24 and 25.

Among those present were Messrs. Bowditch, Boyce, Cushny, Crookshank, Gaskell, Halliburton, Huber, Huerthle, Lee, Loeb, Lombard, Billings, Lister, Macallum, Osler, Wesley Mills, Noël Paton, Porter, Waymouth Reid, Sherrington, G. N. Stewart, Anderson Stuart, Kellog, W. H. Thompson, Charles Richet, Waller, Welby, Shore, MacAlister, O. Grunbaum, Baldwin, Braun, Reynolds Green, Meldola, and A. S. Grunbaum.

Prominent among proceedings in the Section were the following:—

Prof. Bowditch read a paper on the physiology of unstriped muscular tissue as exemplified in the wall of the stomach of the frog. The rhythmic contractility of the tissue is well seen. When the organ or a strip of it is fitted to a recording apparatus, in the majority of instances after a lapse of not more than three hours, contractions of rhythmic recurrence are registered. Often two or more sets of rhythmic contractions are superposed. This may be best accounted for by supposing the muscle-cells to contract not all together but in two or more groups. In the discussion Prof. Sherrington referred to experiments published by him in which had been recorded contractions of the urinary bladder removed from freshly-killed monkeys and placed in warm normal saline solution, while connected with a volume recorder. In these the isolated bladder began to "beat" almost at once, and continued "beating" for an hour or less, at rate somewhat quicker than once a minute. The contractions thus obtained from the viscus only exceptionally displayed the compound character shown in Prof. Bowditch's curves.

Prof. Carl Huber brought forward observations on the cells of the sympathetic system of vertebrates. In Amphibia nearly all sympathetic cells are unipolar. In other vertebrates the prevailing type is multipolar. All sympathetic neurons have one axon only. The dendrites form a network between the cell-bodies of the neurons constituting a ganglion. The axon of each sympathetic nerve-cell becomes either a non-myelinated nerve-fibre (grey fibre) or a fine myelinated nerve-fibre. The fibres of the white rami are axons of cells lying within the spinal cord, and these axons reach the sympathetic ganglia through the white rami, and in the ganglia undergo branching, ending in baskets which enclose the perikarya of the sympathetic neurons. In mammalia and birds the circumcellular baskets are comparatively simple networks of varicose fibrillæ. In Reptilia and Amphibia instead of simple end baskets the fibre is spirally wound and completely contorted. This is the explanation of Beale's spiral fibre in the sympathetic cells of the frog figured by him forty years ago. In all vertebrates the pericellular baskets are intracapsular. Langley and his pupils have shown that an impulse travelling along a spino-sympathetic efferent chain may be blocked in a sympathetic ganglion by the injection of nicotin. This has been applied to practically all regions of the sympathetic by studies carried out on Langley and Sherrington's pilomotor nerve-system. Huber suggests that the nicotin paralyses not the perikarya of the sympathetic neurons, but rather the end baskets of the pre-ganglionic fibres.

Prof. G. N. Stewart brought forward the results of the application of a new modification of his electrical method of determining speed of blood flow to the question of the output of the mammalian heart. The method depends upon the change of resistance to the passage of electric currents through the blood in an artery or vein brought about by injection of blood serum. Serum conducts better than does entire blood. When the blood admixed with serum reaches the point of blood vessel under examination, electric currents previously balanced by a Wheatstone bridge are thrown out of balance, and it is arranged that a telephone shall announce this event. A specimen of blood is drawn from the corresponding artery in the other limb, and from this is determined the amount of serum which must be added to the normal blood to make its resistance equal to that collected during the passage of the mixture. The output of the heart can, from these data, be determined for the period of injection, and consequently by knowing the pulse-frequency be determined for a single beat. In the dog it is about 2·3 c.c. per second per kilogramme of body-weight.

Prof. Townsend Porter gave an account of observations made upon a strip of the muscle of the apex of the dog's ventricle. The strip is left attached only by a band of pericardium, and yet exhibits in this isolated state rhythmic spontaneous beats. The rhythm of its beat is slow but perfectly regular; it is slower than the rhythm of the rest of the ventricle; it, of course, persisted when the rest of the ventricle was arrested by excitation of the vagus nerve. The blood supply was maintained in the strip by means of an artery and vein in the pericardium. The isolation of the strip from the rest of the myocardium is found, even under microscopical examination, to be absolutely complete. The contractions of the isolated piece could not have been caused by excitation by the action-current accompanying the systole of the rest of the ventricle, as the piece was raised freely in the air. The asynchronism of the beat of the isolated strip and rest of the ventricle prove the same thing, also that the strip was not discharged by nerves accompanying the blood vessels to the strip. Other experiments showed that if an artificial circulation of diluted blood be kept up through the extreme apex of the dog's heart excised and hung up on cannulæ the isolated apex will be vigorously, coordinately, and regularly for several hours. Hence it is concluded that the apex and other parts of the mammalian heart possess spontaneous rhythmic contractility, that the cause of rhythmic contraction is not a single localised coordination centre, the mechanism of coordination, whatever it be, being present in all parts of the ventricle.

Prof. Porter also described experiments confirming MacWilliam's statement that the ventricle of the dog's heart can be recovered from fibrillary contractions. The entire heart of the cat can be readily made to recover even after long-continued and violent fibrillary contraction by free and steady perfusion of fresh blood through the coronary vessels.

When a vein on the surface of the ventricle *in situ* in the living animal is incised and the heart slowed by vagus excitation, the flow from the cut vein is much increased during ventricular contraction. The contraction of the cardiac muscle compresses the veins, and to a less extent the arteries, in the substance of the heart. The systole aids the circulation of blood through the heart muscle. On the other hand, observations with minimum manometers on the veins of the heart give no support to the view that the heart acts on the coronary circulation to any extent as a suction-pump, although efficiently as a force-pump. A circulation through the vessels of Thebesius was demonstrated to be sufficient to keep up the rhythmic beat of the right venticle after the coronary arteries have been closed. Ringer's solution will not maintain the activity of the mammalian heart, but diluted fresh defibrinated blood will.

Prof. Waymouth Reid gave an account of his most recent researches on absorption in the intestine. Heidenhain demonstrated the fact that the water, organic and inorganic solids, of serum introduced into the intestine, are absorbed. The experiment was devised in support of the theory that intestinal absorption is possible under conditions in which osmotic transfer is excluded, and it was found that even inspissated serum is absorbed. Heidenhain omitted to measure the hydrostatic pressure on either side of the intestinal membrane, so that the possibility of the result being due to filtration was not excluded; and, indeed, the ancient filtration theory of Lieberkühn has, with the necessary modern histological modifications, been revived of late by Hamburger. In the experiments now described, the animal's own serum (obtained by the centrifugal machine) was introduced into a loop of its intestine, and the hydrostatic pressure in the cavity of the experimental loop, and in a mesenteric vein proceeding from a control loop, filled with "normal saline" solution, observed continuously during the course of the experiment. Prof. Reid now found that water, organic and inorganic solids, are absorbed against considerable excess of hydrostatic pressure in the blood-vessels. (Since the velocity of the blood-stream in capillaries is low, it is taken for granted that the pressure in the capillaries of the intestinal villi is not lower than that in a mesenteric vein at the border of the gut.) The results of his experiments are practically the same when all the lacteals leaving the experimental loop of intestine have been occluded by ligature.

Prof. Reid called attention to our present inability to explain the phenomena. Great difficulties are offered in the face of the following points, examined and proven by his experiments.

(1) Osmosis, filtration into the blood capillaries, or into the lacteals by the action of Brücke's "villus pump" are, it is considered, excluded by the conditions of the experiment.

(2) That the disappearance of the serum from the cavity of the gut is simply a matter of imbibition is in the highest degree improbable, because the cells must be, at the commencement of the experiment, soaked to the highest degree possible in those constituents of the animal's serum which they are capable of taking up.

(3) Electro-osmotic action is again improbable, because secreting membranes produce ingoing electrical currents as well as absorbing membranes; and, to apply such an hypothesis, it would be necessary to assume that the ingoing current of the cells is active in one case (absorption), the outgoing return current in the other (secretion) involving the further hypothesis of some valvular nature of protoplasm with higher "porosity" in the "in-out" direction in the absorbing, and the "out-in" direction in the secreting, membrane.

(4) Finally, any aspirating action of the blood current in the capillaries of the villi is negligible on account of the low velocity of the current in capillary districts of the circulation.

Prof. W. H. Thompson reported on experiments continued under the committee appointed to examine the effects of peptone and its precursors when introduced into the circulation. The experiments had dealt with the influence of pure peptone, of anti-peptone, and of hetero-albumose on coagulation, on blood-pressure, and on vasomotor irritability. Pure peptone was found to delay but not destroy the coagulability of blood, and to cause a fall in blood-pressure and to lower the vaso-muscular irritability. Antipeptone was found to hasten the coagulation of blood: it causes a very transient fall of arterial blood-pressure, which is immediately followed by a long-continued slight increase of blood-pressure above that present at commencement of the experiment. As to deutero-albumose this substance was not found to give constant results: in some experiments a marked retardation, in others a marked increase of rate of coagulation of blood ensued. It causes a considerable fall in the arterial blood-pressure. Further experiments are in progress on the subject.

Prof. Carl Huber brought forward an important and lengthy paper on the modes of ending of nerve-fibres in smooth, cardiac, and striated muscles. Regarding the last-mentioned it was urged that the nucleated "sole" of the motor end-plate is largely an artefact, derived by expression of the interfibrillar substance of the muscle-fibre The mode of ending of the nerve-fibres in the muscle-spindles shows them, in agreement with Sherrington's experiments, to be sensorial end-organs. The methylene-blue method bears out the description of the ending given by Ruffini, and reveals further details of considerable interest.

Prof. K. Huerthle described a method by which the resistance offered by the vascular channels of an organ to the blood-flow through them may be measured The viscosity of the blood which, together with the dimensions of the tubular system, form the two factors on which the resistance depends, was determined by allowing the blood from an artery to flow through calibrated capillary tubes for thirty seconds, the quantity, pressure, and duration of flow being accurately measured. The internal friction of the blood of the dog is about 4·5 and of the rabbit 3·2, that of water being unity. If in any particular organ the quantity of blood flowing through in a unit of time, the arterial pressure, and the coefficient of viscosity be known, it is easy by Poiseuille's law to calculate the bore and length of a tube through which, under given conditions, the same quantity of blood would flow. The aim of the experiments is to measure and express the resistance through the several regions and organs of the body in this manner.

Prof. A. R. Cushny described rhythmic variations in the strength of the contractions of the mammalian ventricle under the action of certain drugs of the digitalis groups. The variations occur only when the ventricle is beating at a rate different from that of the auricle. If the conjunction of the auricular with the ventricular beat fall at a favourable time, the beat of the ventricle is strong; if at an unfavourable, is weak. The systole of the auricles at a certain stage of the rhythm falls at the systole of the ventricle: the auricle in consequence cannot empty itself. It was also pointed out that the action of nicotin on the mammalian heart is exactly similar to its action as discovered by Langley on the ganglia of the sympathetic system.

Prof. Loeb demonstrated experiments on the influence of the discharge of highly-charged conductors on nerve-muscle preparations. It was known that if a highly-charged conductor be discharged in the neighbourhood of a nerve, the muscle contracts. He found in relation to this the following new facts. (1) If the nerve be placed parallel with the spark discharge of a friction machine, maximal effects are obtained when the electrodes are symmetrical in regard to the nerve. If the nerve be set to one side near one electrode the effects decrease. (2) If the nerve be set at right angles with the spark discharge, minimal effects are obtained when the electrodes are symmetrical to the nerve. Strong effects are obtained by placing the nerve near one electrode. (3) By putting a conductor behind the nerve in Case 1, the effects are effaced or diminished. By putting a conductor between the nerve-muscle preparation and one electrode in Case 2, an increase in effect is produced. It had been shown in the last ten years that the phenomena of heliotropism, long observed in plants alone, are common in the animal kingdom. In both cases the effects of the light are determined by the direction of the rays and the length of waves, the more refractive of the visible spectrum being chiefly effective. It is possible to directly stimulate nerve by electric rays. Apparently the galvanic current does not directly act on living matter; its effects as stimulus being in reality only due to the direct or secondary products of electrolysis.

Prof. Waller gave a demonstration and description of the action of various reagents upon the electrotonic currents of nerve. He has succeeded in completely proving that these currents are in the strictest sense physiological, and they therefore become more than ever of high physiological interest. In the frog's nerve the anelectrotonic current considerably exceeds the katelectrotonic in magnitude. The action of acids, of alkalis, of carbonic acid, of some anæsthetics, and also of tetanisation and of variations of temperature were all dealt with in their bearing upon the ratio and magnitude of the electrotonic currents. Slight acidification diminishes the anelectrotonic current and increases the katelectrotonic: treatment with bases diminishes in a typical manner the katelectrotonic current. The effect of prolonged tetanisation upon the katelectrotonic current is similar to that of acidifidation. Its effect, though less uniform on the anelectrotonic current, yet strongly resembles the effect produced by carbonic acid. Prof. Waller, indeed, holds that his experiments bring strong evidence that the tetanisation of nerve induces in the nerve the production of CO_2 to a thus detectible extent. Electrotonic currents are diminished for a time by exhibition of ether vapour, and are rapidly and permanently abolished by weaker percentages of chloroform vapour. In other words, chloroform rapidly kills the nerve outright, while by ether it is easy to merely diminish or abolish the excitability of the nerve for a temporary period.

Dr. Mackay communicated a paper on the absorption of "ferratin" and of hæmoglobin by the intestinal wall. He had used the microchemical tests for iron devised by Prof. Macallum. He found that the iron of ferratin is absorbed by the epithelial cells of the villi, and that it was passed inwards to the leucocytes. Deposits of iron could further be found in the liver, spleen, and lymph glands. The iron of hæmoglobin is absorbed by the epithelial cells as a compound, probably hæmatin. In this case deposits are also found in the organs of the portal system, and there is indication of some excretion of iron in the bile and in the urine.

Dr. Noël Paton read a paper on the phosphorus metabolism of the salmon in fresh water. Sample salmon were throughout the spring, summer and autumn taken from the mouths of certain rivers, and others from the upper waters of the same rivers. Abundant observations clearly show that the fish do not feed during their stay in fresh water. The muscle substance steadily diminishes, while the ovaries and testes grow at its expense. The fats and proteids lost from the muscles are sufficient to supply these materials for the growing genitalia, and to yield a very large amount of energy for muscular work. The question here discussed is the exchange of phosphorus. It is first shown that in muscle the phosphorus is chiefly in the form of inorganic phosphates, though a comparatively large amount of lecithin and a small amount of nuclein are also present. In the ovary the phosphorus is chiefly combined in the pseudo-nuclein—ichthulin; but it is also present in considerable amounts in lecithin, and in very small amounts as inorganic phosphates. In the testis the phosphorus is chiefly in the form of true nucleins, but there are also a considerable quantity of lecithin and a small quantity of inorganic phosphate. As the season advances the phosphorus in the genitalia increases, while the phosphorus of the muscle diminishes. The loss of phosphorus from the muscle is barely sufficient to account for the gain in the ovary, amply sufficient to yield the increase of phosphorus in the testis. The lecithin lost from the muscle is sufficient only to account for a small part of the lecithin gained by the ovary. The lecithin and ichthulin of the ovary must thus be found by synthesis as these structures grow. The nuclein of the testis must be formed in a similar manner.

The presence of considerable amounts of lecithin in the growing ovary and testis would seem to indicate that this substance is one of the first stages in the construction of nucleo compounds.

Prof. W. P. Lombard gave a communication on the effect of frequent excitations on the contractility of striped muscle. When the muscle is made to give a series of contractions the height of the contraction is seen to increase. The muscle contracted very much higher to an induction shock just after than just before a short period of tetanic excitations. Each of a series of short tetani following each other in rapid succession was, until fatigue appeared, higher than its predecessor. The after effect of excitation is to increase the capacity of the muscle to shorten. When the inertia of the writing lever is increased each of a series of short tetani is seen to begin with a sudden high rise, the throw of the lever carrying the curve above the actual shortening of the muscle. The height of the introductory peak exhibits in repeated tetani a staircase-like growth, and this, in spite of the total contraction being lessened by an increasing growth of contracture heightening the base-line. The effect of the repeated excitations is to cause a more and more sudden and intense liberation of energy.

Prof. Sherrington demonstrated the production of an intense colour of subjective origin by whirling a disc coloured with red on a black-white ground. The disc should contain a black sector of about 170°. From one edge of the black sector broad concentric vermilion arcs are carried into the peripheral white part of the discs for about 90°; from the other edge of the disc similar arcs in the central part of the white field. On rotating the disc so that black follows red in the circumferential field, and precedes red in the central, the outer arcs appear a dull dark maroon, the inner a bright orange, and the spaces between the outer arcs appear deep blue-green, and the spaces between the inner arcs appear primrose-yellow, especially when viewed by a yellowish illumination. Prof. Sherrington offered an explanation for the phenomenon which he based on negative after-images heightened by simultaneous and successive contrast-effects which, as he demonstrated at the meeting, take effect even when speed of translation of a surface prevents the mind from perceiving the space-relations of the distribution of the contrasted tints. It was pointed out that the disc is being used in this experiment similarly to a circular rheotome for summation of effects which taken singly would by reason of their small quantity be imperceptible. It was also demonstrated that by whirling the disc at higher speed the phenomenon becomes altered, the reds and greys then matching over the whole surface of the disc, the greys assuming a pale green tint; when this is obtained, it was urged that one factor of those previously acting, namely simultaneous contrast, had alone become valent.

Prof. Halliburton and Dr. Mott made a communication on the effects produced on the arterial blood-pressure by the intravenous injection of choline, neurine, and allied substances. Normal cerebro-spinal fluid produced no effect, while that obtained *post-mortem* from cases of general paralysis of the insane produced a fall of blood-pressure. This is not due to a proteid body present; for after coagulation by boiling, or precipitation by alcohol, a similar effect is produced. Neurine hydrochloride in 0·1 per cent. solution gave a similar fall, but in most cases this was followed by a rise and then by a more persistent fall of blood pressure. Choline hydrochloride in 0·2 per cent. solution gave results identical with those obtained by the pathological cerebro-spinal fluids. Blood taken from patients suffering from pseudo-apoplectiform convulsions of general paralysis was precipitated with alcohol, and the filtrate, after evaporation to dryness and solution in saline, injected, and the effect produced corresponded entirely with that obtained with pathological cerebro-spinal fluids and with solution of choline. Normal blood gave a negative result. The fall of blood-pressure produced by these various reagents is cardiac in origin. This was established by plethysmographic tracings and by experiments on the frog's and mammal's heart. This agrees very well with what is found in general paralysis, cardiac weakness, and enfeebled circulation.

Prof. Richet related experiments by which he had succeeded in showing and measuring in the dog the refractory period of the bulbar and cerebral nervous centres. The animal is cooled down to 30° C. and anæsthetised. It will then react to electrical stimulations of the cortex if the stimulations be not too frequent. If the rhythm of these be 1 per second, the responses are equal in magnitude; if 4 per second, there will be one large and then one small response; if 10 per second, there will be no longer a response to each excitation but one to each alternate. Half of the stimuli fall within a refractory period. The duration of the refractory period is 1/10″. It is possible to show that, as was originally indicated by the experiments of V. Kries, volitional impulses have a frequency of repetition of about 10 or 11 in a second.

Dr. F. S. Lee brought forward the results of his continued researches into the functions of the semicircular canals in fishes, especially in regard to maintenance of equilibrium and to locomotion.

Prof. Anderson Stuart made an interesting communication on the canal of Stilling. He also showed models illustrating the horopter.

Mr. O. Grunbaum contributed a communication upon the effects of intermittent retinal stimulation. He exhibited the results of several series of experiments stated in curves with measures of speed of alternation as ordinate-heights and degrees of illumination as abscissæ. The curves so obtained possess each an apex above, denoting that a sensation of continuous stimulation results if the luminosity be below or beyond a certain amount. The curve begins to descend some distance prior to the use of a degree of luminosity such as to produce a blinding after-image.

Dr. A. Grunbaum gave a communication on muscle spindles found in human muscles; the communication was illustrated by microphotograms.

Profs. Boyce and Herdman contributed the results of their investigations on "green oysters." They had demonstrated copper in comparatively large quantity in the green leucocytes of the American oyster. The green colour in these oysters is in direct proportion to the copper present. The copper indicates a pathological condition of these American oysters. They were not prepared to state whether copper in the food of the oyster can bring about the condition, but there is abundant evidence to show that it can occur where no copper mines or other evident sources of copper are present. The normal copper of the hæmocyanin of the blood, which is probably constantly circulating through the body in minute quantity, may cease to be removed, and so become stored in certain cells in the oyster. The deposition of the copper in the large quantity found appeared to them the result of a degenerative process.

Prof. Boyce communicated a paper by Dr. Warrington (Liverpool). The effects of ischœmia on the structural features of nerve-cells were shown to be very marked. Also the effect of cutting off from the anterior coronal cells the afferent impulses usually impinging on them was studied in cases where the posterior roots had been divided. Marked changes were found, which were minutely described. On the other hand, attempts to discover changes in the cells of the oculomitorius and facialis nuclei after section of their nerve-trunks failed to detect any changes.

In experiments of the kind mentioned above, in which changes uniformly resulted, the typical picture of alteration is very characteristic; the cell becomes somewhat enlarged, is stained red, with a small amount of blue chromophitic granules at its periphery, the nucleus remaining well-marked. The changes go on to a further swelling up of the cell, a disappearance of its nucleus, and finally shrinkage and ultimate disappearance. The paper was illustrated by microphotographs. The method of staining of the preparations employed had been the methylene-blue and erythrosin modification of Nissl's stain.

Prof. Macallum made a long and important communication on the structures of the nucleus and body of the cell, and described the views at which he had arrived on this profound and difficult subject.

Prof. Wesley Mills contributed interesting papers on the psychic development of young animals, on the functional development of the cerebral cortex, and on cortical cerebral localisation.

Miss F. Welby contributed an interesting account of observations on the effect of curvesthetic vapours on the cardiac muscle of the frog; her remarks being illustrated by the projection of the graphic records of the experiments.

The morning of Tuesday, August 24, was devoted to a combined meeting of the sections Physiology and Botany to discuss the chemistry and structure of the cell. Several members of the section of Chemistry also took part, the opening paper being by Prof. Meldola. Profs. Marshall Ward, Armstrong, Green, Macallum, Remsen, Farmer, and Halliburton, spoke in the discussion.

Prof. Meldola devoted his opening paper to a discussion of the *rationale* of chemical synthesis of bodies formed by living organisms.

The presidential address by Prof. Foster was given in the large Zoology Theatre of the University; it was very numerously attended. It was a retrospect of the history of physiology since the previous meeting of the British Association at Montreal in 1884. It was pointed out that the opportunities for studying physiology had grown larger and more facile. "But there is still a larger outcome from the professional chair and physiological laboratory than the training of students. Each post for teaching is no less a post for learning. Among academic duties the making of knowledge is no less a duty than the distributing of it." "Practical expression has been given to this feeling more vigorously in Canada and the United States than in the old country." "Physiology is destined, in consequence of its containing the study of the actions of the brain, to modify the attitude of the physiologist toward the world, and of the world toward the physiologist. That physiology is, and must always be the basis of the art of healing is a truism, but if a plebiscite limited to instructed, one might almost say scientific, men were taken at the present moment, it would probably enough be found that the most prevalent conception of physiology is that it is something which is in some way an appendage to the art of medicine." But without plunging "into the deep waters of the relation which body bears to mind, this at least stares us in the face that changes in what we call the body bring about changes in what we call the mind. When we alter the one we alter the other. . . . If, as the whole past history of our science leads us to expect, in the coming years a clearer and clearer insight into the nature and conditions of that molecular dance which is to us the material token of nervous action, and a fuller exacter knowledge of the laws which govern the sweep of nervous impulses along fibre and cell, give us wider and directer command over the moulding of the growing nervous mechanism and the maintenance and regulation of the grown one, then assuredly physiology will take its place as a judge of appeal in questions not only of the body, but of the mind; it will raise its voice, not in the hospital and consulting room only, but also in the senate and the school."

ON THE SUMMIT OF MAUNA LOA.

DR. H. B. GUPPY has contributed to the *Pacific Commercial Advertiser*, published at Honolulu, an account of observations made during a three weeks' sojourn upon the summit of Mauna Loa in August last.

The air at first was highly electrified. A red blanket used by Dr. Guppy crackled under his hands at night, and he could trace letters on its surface in phosphorescent hues with his finger-nail as he lay completely enveloped in its folds. The effects of these meteorological conditions soon showed themselves in the cessation of the action of the skin, in severe headaches and sore-throat; in a tendency to palpitation and dyspnœa, and in sleeplessness, general lassitude and loss of appetite, most of which symptoms were attributed to the great lack of moisture in the air, for when a short spell of damp weather intervened, most of the unpleasant symptoms disappeared. An interesting phenomenon was observed every morning and evening. For about twenty minutes after sunrise and before sunset the shadow of the mountain was thrown back against the sky of the opposite horizon. It seemed as if some artist had been at work on the sky far away, and had painted in the profile of the mountain with a very uncanny blue.

Dr. Guppy's observations on the relative humidity have yet to be worked out, but he remarks that there was occasionally as much as a difference of 20° between the wet and dry bulb thermometers, the usual difference being 10° to 15°. The lowest temperature recorded at night was 15° F., and the minimum reading was usually below 20°. The average minimum temperature for the period, August 9 to 31, was 23°·5. The highest temperature of the air in the shade was 61°·2, the average maximum daily being 53°·6, which places the average difference between the night and day temperature at 30°. This great daily range is about twice what it is at the coast.

State of the Crater.

In order to familiarise himself with the principal features of the crater, Dr. Guppy adopted the method of making a rough plan of it with a pocket prismatic compass. In some places the lava crust was thin and fragile, and although he never descended further than his waist, there was always in such localities a chance of a sudden descent into a cavern of considerable depth.

His descent into the crater was made on the north-west side. It was a tedious operation, and the loose boulders had to be trodden on very carefully, as they are often inclined to roll down and crush the intruder. As soon as Dr. Guppy reached near the centre of the great pit the clouds began to pour in on all sides over the lips of the crater. In a few minutes he was enveloped in a dense mist, and any further observation was rendered impracticable. During the prevailing dry clear weather with a cloudless sky, "smoke" is only evident in two places in the crater, one near the centre and the other in the south-west corner from the base of a yellowish cliff, where there are apparently extensive deposits of sulphur. When, however, the sky is clouded, and especially when the air is moist, white vapour may be seen arising from the greater part of the surface of the crater. The change is a little startling, the true explanation being that a large amount of the vapour evolved is only visible in cloudy murky weather. It is, therefore, possible that the accounts of two observers may vary greatly as to the crater's condition, and yet no difference in the condition actually exist. This especially applies to the district on the south and south-west borders of the crater, stretching about a mile to the southward. In cloudy weather white vapour arises from many places in this area. In the bright clear weather that prevails the visitor may see nothing, and even walk unwittingly over numerous cracks and fissures whence the invisible vapour is being discharged. Dr. Guppy took the temperature of several of these fissures. In those where the vapour was only seen in cloudy weather the temperature was about 104° F. When the "smoke" is always visible the temperature is far higher, 160° F. and over. Many of these cracks and fissures exhibit evidence of having originally given passage to vapours at a very high temperature. The subterranean heat appears now more actively displayed in the district extending a mile to the south of the big crater than in the crater itself. A very large amount of vapour is discharged from the borders of a small crater lying near Pohaku Hanalei, and this is probably the smoke sometimes observed from the Kona coast. It is probable that the next eruption will occur on this, the south south-west slope of the mountain.

Insect Life on the Summit.

Curiously enough, insects of various descriptions are common on the summit. One species of butterfly common at the coast is not at all infrequent. The butterflies were more often to be found dead than alive, and those flying about were in a half-drowsy condition and easily caught. There were flies of different kinds, the house-fly and the blue-bottle-fly proving a great nuisance. Besides these there were moths, bees, gnats, and an occasional dead dragon-fly; whilst bugs and other insects were collected as they fed upon the bodies of the dead butterflies. These insects were more common when the wind was southerly, and no doubt they had been brought up to this absolutely sterile region by the wind. Evidently most if not all of the butterflies and moths soon die, and probably the other insects too. The whole matter is, however, very suggestive, and shows how readily insects (even the parasitical bug) may find their way into the upper air-currents.

PALESTINE EXPLORATION.[1]

The object of exploration is to obtain accurate knowledge of a country, its inhabitants, and its extant monuments and texts. That of Palestine has special interest to Christian races and to Jews, as serving to explain more clearly the sacred literature of their faith.

The results of such exploration may be judged by looking back a century to the time of Bayle, Voltaire and Astruc, when what was regarded as advanced scientific work assumed that the Hebrews were a savage race without literature, that history only began to be written about 500 B.C., and that the oldest civilisation was that of China and India. It is now known that the art of writing was practised in Egypt and Chaldea as early as 3000 B.C., that the Canaanites about the time of Joshua had a civilisation equal to that of surrounding nations, as had also the Hebrew kings; while, on the other hand, Chinese civilisation is only traceable to about 800 B.C., and that of India was derived from the later Persians, Arabs and Greeks. These results are due solely to exploration.

The requirements for exploration demand a knowledge not only of Syrian antiquities but of those of neighbouring nations. It is necessary to understand the scripts and languages in use, and to study the original records as well as the art and architecture of various ages and countries. Much of our information is derived from Egyptian and Assyrian records of conquest, as well as from the monuments of Palestine itself. As regards *scripts*, the earliest alphabetic texts date only from about 900 B.C., but previous to this period we have to deal with the cuneiform, the Egyptian, the Hittite and the Cypriote characters. The explorer must know the history of the cuneiform from 2700 B.C. down to the Greek and Roman age, and the changes which occurred in the forms of some 550 characters originally hieroglyphics, but finally reduced to a rude alphabet by the Persians, and used not only in Babylonia and Assyria but also as early as 1500 B.C. in Asia Minor, Syria, Armenia, Palestine, and even by special scribes in Egypt. He should also be able to read the various Egyptian scripts—the 400 hieroglyphics of the monuments, the hieratic, or running hand of the papyri, and the later demotic. The Hittite characters are quite distinct, and number at least 130 characters, used in Syria and Asia Minor from 1500 B.C., or earlier, down to about 700 B.C. The study of these characters is in its infancy. The syllabary of Cyprus was a character derived from these Hittite hieroglyphics, and used by the Greeks about 300 B.C. It includes some fifty characters, and was probably the original system whence the Phœnician alphabet was derived. As regards alphabets, the explorer must study the early Phœnician, and the Hebrew, Samaritan and Moabite, with the later Aramean branch of this alphabet, whence square Hebrew is derived. He must also know the Ionian alphabet, whence Greek and Roman characters arose, and the early Arab scripts—Palmyrene, Nabathean and Sabean, whence are derived the Syriac, Cufic, Arabic and Himyaritic alphabets.

As regards *languages*, the scholars of the last century had to deal only with Hebrew, Aramaic, Syriac, Coptic and Greek, but as the result of exploration we now deal with the Ancient Egyptian whence Coptic is derived, and with various languages in cuneiform script, including the Akkadian (resembling pure Turkish) and the allied dialects of Susa, Media, Armenia and of the Hittites; the Assyrian, the earliest and most elaborate of Semitic languages; and Aryan tongues, such as the Persian, the Vannic and the Lycian.

The *art and architecture* of Western Asia also furnishes much information as to religious ideas, customs, dress and history, including inscribed seals and amulets, early coins and gems. The explorer must also study the remains of Greek, Roman, Arab and Crusader periods, in order to distinguish these from the earlier remains of the Canaanites, Phœnicians, Hebrews,

---

[1] A discourse at the Royal Institution by Lieut. Colonel C. R. Conder.

Egyptians and Assyrians, as well as the art of the Jews and Gnostics about the Christian era, and the later pagan structures down to the fourth century A.D.

The monuments actually found in Palestine are few though important. The discovery at Tell el Amarna of about 150 letters written by Phœnicians, Philistines and Amorites—and in one case by a Hittite prince—to the kings of Egypt, proves, however, the use of cuneiform on clay tablets by the Syrians as early as 1500 B.C., and one such letter has been recovered in the ruins of Lachish. The oldest monuments referring to Syria and Palestine are found at *Tell Loh*, on the Lower Euphrates, and date from 2700 B.C. Next to these are the *Karnak* lists of Thothmes III. about 1600 B.C., recording the names of 119 towns in Palestine conquered after the defeat of the Hittites at Megiddo. These lists show that the town names which occur in the Bible are mainly Canaanite and were not of Hebrew origin. The Canaanite language of this period was practically the same as the Assyrian, excepting that of the Hittites, which was akin to the Akkadian. In the next century the Tell el Amarna tablets show that the Canaanites had walled cities, temples, chariots, and a fully developed native art. They record the defeat of the Egyptians in the north by Hittites and Amorites, and the invasion of the south by the Abiri, in whom Drs. Zimmern and Winckler recognise the Hebrews, the period coinciding with the Old Testament date for Joshua's conquest.

An inscription of Mineptah, discovered in 1896, speaks of the Israelites as already inhabiting Palestine about 1300 B.C., and agrees with the preceding. Other Egyptian records refer to the conquests of Rameses II. in Galilee and in Syria, when the Hittites retained their independence; and in the time of Rehoboam, Shishak has left a list of his conquests of 133 towns in Palestine, including the names of many towns noticed in the Bible.

The Hittite texts found at Hamath, Carchemish and Merash, as well as in Asia Minor, belonged to temples, and accompany sculptures of religious origin. They are still imperfectly understood, but the character of the languages, the Mongol origin of the people, and the equality of their civilisation to that of their neighbours, have been established, while their history is recovered from Egyptian and Assyrian notices. The Amorites were a Semitic people akin to the Assyrians, and their language and civilisation are known from their own records, while they are represented at Karnak with Semitic features.

The oldest alphabetic text is that of the Moabite stone about 900 B.C. found at Dibon, east of the Dead Sea, on a pillar of basalt, and recording the victories of King Mesha over the Hebrews, as mentioned in the Bible. Several Bible towns are noticed, with the name of King Omri, and the language, though approaching Hebrew very closely, gives us a Moabite dialect akin to the Syrian, which is preserved in texts at Samalla, in the extreme north of Syria, dating from 800 B.C. The Phœnician inscriptions found at Jaffa, Acre, Tyre, Sidon, Gebal and in Cyprus do not date earlier than 600 B.C., and show us a distinct dialect less like Hebrew than the Moabite. The most important of these early texts is the Siloam inscription in the rock-cut aqueduct above the pool, found by a Jewish boy in 1880. It refers only to the cutting of the aqueduct (in the time of Hezekiah), but it gives us the alphabet of the Hebrews and a language the same as that of Isaiah's contemporary writings. It is the only true Hebrew record yet found on monuments, and confirms the Old Testament account of Hezekiah's work.

The Assyrian records refer to the capture of Damascus by Tiglath Pileser III. in 732 B.C., and of Samaria in 722 B.C., as well as to Sennacherib's attack on Jerusalem in 702 B.C. The latter record witnesses also the civilisation of the Hebrews under Hezekiah, whose name occurs as well as those of Jehu, Azariah, Menahem, Ahaz, Pekah, and Hosea, who, with Manasseh, gave tribute to Assyrian kings.

About the Christian era Greek texts occur in Palestine, the most important being that of Herod's Temple at Jerusalem, forbidding strangers to enter, and those of Siah in Bashan, where also Herod erected a temple to a pagan deity. Such texts are very numerous in Decapolis, where a Greek population appears to have settled in the time of Christ.

The geographical results of exploration are also important for critical purposes. Out of about 500 towns in Palestine noticed in the Old Testament, 400 retain their ancient names, and about 150 of these were unknown before the survey of the country in 1872-82. The result of these discoveries has been to show that the topography of the Bible is accurate, and that the writers must have had an intimate knowledge of the land. Among the most interesting Old Testament sites may be mentioned Lachish, Debir, Megiddo, Mahanaim, Gezer, and Adullam as newly identified; and of New Testament sites, Bethabara, Ænon, and Sychar, all noticed in the fourth Gospel.

The existing Hebrew remains are few as compared with Roman, Arab, and Norman ruins of later ages. They include tombs, aqueducts, and fortress walls, with seals, weights, and coins. The most important are the walls of the outer court of Herod's great temple at Jerusalem, with his palace at Herodium, and buildings at Cæsarea and Samaria. The curious semi-Greek palace of Hyrcanus at Tyrus in Gilead dates from 176 B.C. In Upper Galilee and east of Jordan there are many rude stone monuments—dolmens and standing stones—probably of Canaanite origin, as are the small bronze and pottery idols found in the ruins of Lachish. Sculptured bas-reliefs are, however, not found in Palestine proper, having been probably destroyed by the Hebrews.

This slight sketch may suffice to show the advance in knowledge due to exploration during the last thirty years. The result has been a great change in educated opinion as to the antiquity of civilisation among the Hebrews and Jews, and as to the historic reliability of the Bible records. Further exploration, especially by excavation, may be expected to produce yet more interesting results, and deserves general support, as all classes of thinkers agree in the desirability of increasing actual knowledge of the past. It is no longer possible to regard the Hebrews as an ignorant and savage people, or to consider their sacred writings as belonging necessarily to the later times of subjection under the Persians. Internal criticism is checked and controlled by the results of exploration, and by the recovery of independent historical notices.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Walsingham Medal, given by the Lord High Steward, for original research in botany, geology, zoology, or physiology, is open to all graduates of the University under the standing of M.A. Monographs for the ensuing year are to be sent to Prof. Newton, Magdalene College, by October 10, 1898.

An examination for the Sheepshanks Astronomical Exhibition will be held in Trinity College on November 19 and 20. In addition to papers on astronomy, there will be an oral and practical examination at the Observatory. Candidates must be undergraduates, and, if successful, must become members of Trinity College.

Mr. G. H. A. Wilson, fifth wrangler 1895, has been elected to a fellowship at Clare College.

PROF. JAMES M. CRAFTS, professor of organic chemistry in the Massachusetts Institute of Technology, will succeed the late General Francis A. Walker as the president of the Institute.

THE *London Technical Education Gazette* announces that a course on practical chemistry, dealing with the "manipulation of gases," will be conducted by Mr. M. W. Travers, at University College, on Fridays, at 5.30 p.m., commencing on Friday, November 12. This course will be of great value to those engaged in gas testing, and will deal with methods not hitherto published. A research course for teachers on "The effect of repeated heating on the magnetic permeability and electrical conductivity of iron and steel," is being conducted by Principal Tomlinson, F.R.S., at the South-west London Polytechnic, Manresa Road, Chelsea, on Saturday mornings from 10 to 1, with facilities for continuing experiments, if desired, from 2 to 5. Teachers are admitted free; there are still a few vacant places in the class. Any teachers who wish to join should apply at once to Principal Tomlinson.

THE first volume of the Report of the United States Commissioner of Education, for the year 1895–96, has been received. Though largely concerned with elementary schools, the report contains several noteworthy articles on the higher branches of education. A detailed account is given of the Education Bill of 1896, and the discussions which led to its withdrawal. Current statistics of education in Great Britain form the subject of a special chapter. Some of the features of the educational systems of Germany, Austria, and Switzerland are reported upon, the statistics which the report gives as to higher education in the German-speaking part of Europe being very valuable. It appears from the extensive tables contained in the report that there are 75 higher seats of learning in Germany, Austria proper, and Switzerland, having altogether 5963 professors, 67,062 students, and 6628 foreign students. There is in Germany one professor for 12·1 students, and an average of 78·4 professors and 926·3 students (of whom 67·2 are foreigners) to one seat of learning. Austria has one professor for 11·7 students, and an average of 80·5 professors and 949·4 students (of whom 91·1 are foreigners) to one higher seat of learning. Switzerland has one professor for 5·9 students, and an average of 96·2 professors and 569·6 students (of whom 208·3 are foreigners) to one higher seat of learning. Among other subjects of articles in the report are: the comparative study of popular education among civilised nations; education in France; education in Mexico and Central America; commercial education in Europe, particularly in Austria, France, and Germany; and the correlation of studies.

One of the most gratifying signs of educational progress is the increasing efficiency of technical institutions in the provinces as well as in London. These schools are not only far better equipped than they were a few years ago, but in many cases the members of the teaching staffs are better qualified to impart instruction. The prospectuses and calendars which come before us from time to time testify to a real development of facilities for education in science and technology, and we are glad to observe the advances which technical schools are making all over the country. A prospectus just received from the Technical College, Huddersfield, furnishes an instance of valuable work being done in a large technical college outside London. This college provides full courses, both theoretical and practical, and of an advanced type, in physics, chemistry, biology, art, engineering, weaving and dyeing. There are also separate departments for mathematics, languages ancient and modern, and commercial subjects; whilst a mining section is in process of formation. Of especial importance is the fact that the college library consists of some 10,000 volumes, an annual sum of 160*l.* being devoted towards the purchase and binding of books, periodicals, &c. At the present time an extension, calculated to cost about 13,000*l.*, is being carried out. Improved accommodation will thus be provided for chemistry and physics, and engineering; a room 105 feet by 27 feet has also been set aside for a museum for biology and mineralogy. The number of students of both sexes for the last two or three years averages about twelve hundred. Students can at present take up at the college all the subjects required by the London University for a degree in art or science, and they will be able to continue to their D.Sc. work when the new chemical and physical laboratories are completed. In all departments we notice that practical work is carried on as well as lectures. Dr. S. G. Rawson, the principal, appears to be developing the college on the right lines, and Huddersfield will doubtless benefit by the work he is doing. Financially the college is also in a satisfactory condition. We think both council and staff are to be congratulated upon the care and energy which has been displayed in building up so strong and useful an institution.

SOCIETIES AND ACADEMIES.

London.

Physical Society, October 29.—Mr. Shelford Bidwell, President, in the chair.—Prof. Stroud exhibited and described the Barr and Stroud "range-finder." The problem of finding the distance of a given object at sea, or in the field, is complicated by shortness of the trigonometrical "base," and by restrictions of time. As a rule, the apparatus must be self-contained, and "snap-shot" readings are obligatory, *i.e.* the range has to be determined from a single instrument and from a single observation. At 3000 yards the errors must not exceed 3 per cent. In foggy weather, or when viewing a nebulous object, this degree of precision is difficult to attain, but under favourable circumstances the authors have determined ranges, at that distance, within 1 per cent. of accuracy. At shorter ranges measurement is more exact; thus an object at about 2000 yards may be estimated to within about 12 yards. Prof. Stroud gave some account of the history and of the general methods employed in these instruments. Two images of the distant object, preferably of a line such as a flag-staff, are received respectively upon two mirrors, two lenses, or two prisms, placed one at each end of a fixed support. From each of these, the light is then directed towards the middle of the instrument, where the two images, after further reflection, are viewed by one eye-piece. The optical system has finally to be adjusted so that the two images, as now seen in the eye-piece, lie in the same straight line. In the instrument designed by the authors this coincidence is attained by translating a small prism parallel to the axis of the supporting rod. The extent of this translation is a measure of the range. Both eyes are used: the right for bringing the two images into alignment; the left for "finding" the object through a small field-glass, and for reading the scale of distances. At night, sightings have to be taken from "points" of light, and as these are unsuited for measurement, the authors convert them into "lines" by the use of cylindrical lenses. Various devices are introduced to prevent overlapping of the images. The instrument is about five feet long, and tubular in form; it is made of copper, so as to have high thermal conductivity to reduce differential heating. Within the outer tube is the interior supporting rod, designed to equalise so far as possible the effects of interior radiations. Several forms of "separating" prisms were exhibited, the best for the purpose consists of two "reflecting" prisms; these receive the two rays and direct both of them into a third prism, whose angle lies in the space between the angles of the others. Mr. Barr drew attention to the gimbal arrangement and the three struts that keep the supporting rod centred in the tube. To give some idea of the precision and scope of the range-finder, he observed that they were there using the equivalent of a 25-feet "circle," and their measurements were comparable to the measurement of 20 secs. of angle on such a circle. The instrument is handled by ordinary seamen, and stands rough usage on board ship for years without injury.—Prof. Stroud then exhibited "a folometer and spherometer." He explained that in determining curvatures and focal lengths, some telemetric method was necessary, and that, owing to want of parallelism of the beam, and duplication of images, a short-focus telescope was always an inefficient telemeter. For the measurement of inaccessible lengths it was therefore better to use some simple form of "range-finder." Such an apparatus could be made with a set of small mirrors arranged in such a manner as to direct two images of the distant object into an eye-piece, with a fixed prism in the path of one of the incident beams. By sliding this instrument along the optical bench one position could always be found at which the two images, as seen through the eye-piece, were in coincidence. He also described a method for determining curvature by interposing a plate of plane glass between the curved mirror and a source of light.—Mr. Ackermann exhibited two experiments. (1) The blowing-out of a candle-flame by the air from a deflating soap-bubble. The bubble was blown at the mouth of an inverted beaker by breathing into a hole cut out at the top. This hole was then presented to the flame, and the flame was immediately quenched. But if the bubble was blown from ordinary air, with bellows, the flame was merely deflected without being extinguished. (2) It was shown that a miniature boat, provided with a false stern, consisting of a linen diaphragm, could be propelled by filling the hollow stern-space with ether, or with some liquid similarly miscible with water. The motion is due to the continuous release of surface-tension behind the boat. Prof. Boys said that when he tried, some years ago, to blow out a candle with a soap-bubble filled with common air, he found the operation very difficult—so difficult that, having once succeeded, he never repeated the attempt. It had not occurred to him, as it had to Mr. Ackermann, that the CO_2 present in the breath played a part in the quenching. With regard to the second experiment, he had seen a small boat propelled by dissolving camphor astern, but he thought the use of a liquid for that purpose was a novelty.—The President proposed votes of thanks, and the meeting was adjourned until November 12.

Paris.

Academy of Sciences, October 26.—M. A. Chatin in the chair.—Apparatus for measuring the altitudes attained by balloons. Verification of the results furnished by barometers, by M. L. Cailletet. The dial of the aneroid is placed exactly in the focus of a photographic camera, to which such a mechanism is fitted that every two minutes two photographs are taken simultaneously, one of the barometer and another of the earth. From the focal length of the photographic objective, the distance of any two points on the earth, and the distance of these two points on the negative, the calculation of the true height is easily calculated. The apparatus worked perfectly in a preliminary balloon ascent made by MM. Hermite and Besançon.—Report on a memoir of M. Hadamard, entitled

“On the geodesic lines of surfaces of opposite curvatures,” by M. H. Poincaré.—Observations on the new Perrine comet (1897, October 16), made at the Observatory of Paris, by M. G. Bigourdan.—Observations of the same comet made at the Observatory of Toulouse, by M. F. Rossard.—On the deformation of quadrics, by M. C. Guichard.—On systems completely orthogonal in space of n dimensions, and on the reduction of more general differential systems, by M. Jules Drach.—On Weingarten surfaces, by M. A. Pellet.—On a new method of reducing the time of exposure in radiography, by M. Gaston Séguy. A thin glass plate is coated on both sides with an emulsion of gelatino-silver bromide, and allowed to dry. This is then enclosed between two flexible screens, formed by M. Becquerel's calcium violet in suspension in celluloid, and the whole pressed together between cards. A photograph of the thorax, using a six-inch coil, with thirty seconds' exposure, was completely satisfactory, every detail being shown with great clearness.—On a new bianodic bulb, with a red phosphorescence. The glass of the bulb is tinged with didymium chloride. The fluorescence is red instead of green, giving twice as much of the X-rays as ordinary glass. The effects on the screen are very brilliant, and can be seen by persons colour-blind to green.—Researches on saline solutions; lithium chloride, by M. Georges Lemoine. Thermal data, showing the heat of dilution of solutions of lithium chloride in water, methyl and ethyl alcohols.—On some basic salts of magnesium, by M. Tassilly. The preparation and properties of the oxybromide $MgBr_2.3MgO.12H_2O$ is described.—The separation and direct estimation of chlorine and bromine in a mixture of alkaline salts, by MM. H. Baubigny and P. Rivals. The separation is effected by potassium permanganate in presence of a large excess of copper sulphate. Analytical results are given, showing the trustworthiness of the method under varying conditions.—On some combinations of metallic acetates with phenylhydrazine, by M. J. Moitessier. Double salts are formed with phenylhydrazine by the acetates of zinc, cadmium, manganese, cobalt, and nickel.—The methods of estimating diabetic sugar, by M. Frédéric Landolph. A comparison of the results obtained in the estimation of diabetic sugar by the polariscopic, fermentation, and copper reduction methods, showed that only the optical can be depended upon.—Optical and reducing power of the flesh of flies, by the same.—Action of the X-rays upon the cutaneous evaporation, by M. L. Lecercle. In the rabbit, the evaporation of a given portion of the skin can be almost completely suppressed, and the effects continue for some time after the exposure. On the human hand, evaporation is somewhat checked, but the action is fugitive, and the evaporation rapidly recovers its original value.—On yellow fever, by M. le Dr. Domingos Freire. A description of the habits and mode of growth of the bacillus, *Micrococcus xanthogenicus*. Attenuated cultures of this bacillus, injected into animals and man, produce a mild form of yellow fever, which confers immunity from the disease. Since 1883 some 13,000 persons have been inoculated, of all ages and nationalities. The subsequent mortality from yellow fever, in spite of violent epidemics which have raged, has not exceeded six per thousand.—Observations on the circulation of the Amphictenia, by M. Pierre Fauvel.—On the differentiation and development of the woody elements, by M. L Jules Léger. The discovery of a Miocene bat at Grive-Saint-Alban, by M. Claude Gaillard. A complete humerus, and some fragments were discovered.—On the Armand cave, by MM. E. A. Martel and A. Viré. A description of the results of the exploration of a subterranean cave, 207 metres deep, the most remarkable feature being a forest of two hundred stalagmitic columns, of heights varying between three and thirty metres.

DIARY OF SOCIETIES.

MIMICRY IN BUTTERFLIES AND MOTHS.[1]

Researches on Mimicry on the Basis of a Natural Classification of the Papilionidæ. Part ii. *Researches on Mimicry.* By the late Dr. Erich Haase, Director of the Royal Siamese Museum in Bangkok. Translated by C. M. Child, Ph.D. Pp. 154, and 8 coloured plates. (Stuttgart: Ernin Nägele. London: Baillière, Tindall, and Cox, 1896.)

II.

WE have now to inquire as to the treatment accorded to Haase's work by publisher, translator, and editor.

The eight coloured plates are perhaps the most satisfactory feature of the work as it appears in this country. The English translation is limited to Part ii. of Haase's complete memoir, of which the plates still retain the numbering, viz. 3, 4, 9, 10, 11, 12, 13, and 14. In spite of this, there are frequent references in the text to the other plates (*e.g.* Plate i.) without the slightest indication that the plate in question is not to be found. This is all the more tantalising inasmuch as some of the most interesting figures, viz. those of *Papilio merope* and its allies have their place in the omitted plates.

References to the parts which are not translated appear in the irritating form of "Part i., pages — —," the exact page of the German original being given in the margin, or, as on p. 35, withheld altogether.

The quality of type and paper leave nothing to be desired, and it is very unfortunate that these great advantages should be rendered of little avail for the want of an intelligent proof-reader, to say nothing of an editor.

The names of authorities quoted are frequently misspelt: thus, Jenner Weir appears as J. Wier on p. 12, while on p. 20 it is rendered J. Weis; de Saussure is de Saussare (p. 6); Grose-Smith is rendered by Grosse-Smith (p. 84); Mansel Weale by Wheale (pp. 45 and 104); J. W. Slater by J. W. Sclater (p. 95); while in the footnote of the same page the name appears as F. M. Sclater. Mr. A. G. Butler and the present writer are let off comparatively easily with the initials A. E. B. (p. 33) and E. G. P. (p. 20).

Even more misleading are the frequent mistakes in scientific names, such as *candata* for *caudata* (p. 32), *Euploræ* for *Euplœæ* (p. 25), *Argynns* for *Argynnis* (p. 119), *Decopeia* for *Deiopeia* (p. 98), *biconius* for *bicornis* (p. 147), *Cheysomelid* for *Chrysomelid* (p. 137), *Glancopid* for *Glaucopid* (p. 73), &c. Then avian is rendered by arian (p. 126), while genus becomes ganus (p. 137). The words Pierinæ and Pieridæ are both used; but the combination of these into Pieridinæ (p. 64) is, I believe, peculiar to this volume. A conspicuous and important position is no guarantee against the most absurd errors. In the heavily-printed headings of important sections of the work, Coleoptera appears as Colcoptera (p. 18), Mimetic as Numetic (p. 19), and Hypolimnas as Hypolinopas (p. 29).

After this it is hardly necessary to allude to the innumerable blunders in ordinary words which are scattered thickly throughout the work. Some of these mistakes are, however, worthy of quotation merely to illustrate some of the curious forms which printers' errors may assume. Thus we meet with "altoogether to slight" (p. 137), while "exclusively" becomes "exclusive by" (p. 119); in "a bee" the words are transposed and fused, becoming "beea" (p. 72). In many cases the wrong letter makes a different word, which may sometimes be mistaken for that which was intended. Thus "ledges" becomes "lodges" (p. 7), "wavy" becomes "wary" (p. 148), "than" becomes "then." It is an interesting speculation to attempt to determine the intended word in the passage which tells us that the Jamaican *Aristolochia grandiflora* emits such an unpleasant smell that "even pigs she from eating it" (p. 97).

Errors of punctuation also occur, sometimes producing the most ludicrous effect, sometimes merely serving to confuse the reader. The Zygænidæ are described as possessing "large legs beset with numerous spines and short antennæ" (p. 73). A good example of the difficulties introduced by want of style and want of correct punctuation is to be found in a sentence on p. 123: "This similarity among inedible species is, as first pointed out by Fritz Müller and Wallace, *mutually advantageous* to the participants in the resemblance for the type of the immune forms becomes in this way *more distinct*, being expressed in few forms." The reference number is so displaced on p. 98, that "Indian Danaids" appear in the footnote as "this sluggish little Bombycid," and it becomes a matter of conjecture as to the insect which is really intended—probably *Deiopeia*. On p. 14 *centrali* is hyphened with *Biologia* instead of with *americana*.

The names of species are generally printed in italics, but curious exceptions occur. Thus on p. 127 the generic name of a species is printed in ordinary type, the specific in italics, an arrangement which is reversed with another species on p. 55; while on page 58, half of the word Passifloræ is printed in one way and half in the other.

We have now to judge how far the translator has given us a fair idea of the immense amount of labour which the author bestowed upon his work. The two chief and essential qualifications for a translator are (1) the knowledge of the two languages, and especially of that into which the work is being rendered; (2) knowledge of the subject-matter, without which the most skilled linguist must come hopelessly to grief.

The knowledge of English possessed by the translator of Haase's work may be inferred from the frequency with which a sentence is preceded by an unnecessary and inexplicable "thus," by the use of the word "momentarily" where we should say "temporarily" (114), of "irrelevant" for "unrelated to" (136), of "aside from" for "besides." On p. 105 it is suggested that the "secondary shading of the wings" of certain butterflies may be "a reaction of the *morbidly sensitive* organism against the physical and chemical influences of the hotter climate." On p. 100, pupæ are said to be protected "by often very artistic cocoons."

All those who see much of children at Christmas-time will have had occasion to notice the printed directions accompanying toys which bear a familiar legend. It will often be observed that these directions remain as a constant source of amusement long after the toys themselves have come to their natural end in the dustbin.

---

[1] Continued from p. 4.

Any one who is familiar with this class of literature will probably infer that the following sentences were also "made in Germany."

> "Trimen also observed that an Acacia tree with exuding sap, the sporting ground of the sucking insects, was also visited by predatory Mantids, which found here numerous victims" (p. 40).
>
> "I regard these females therefore, not as does Butler, as mimics of the *Euplœæ*, but as normally coloured, for they resemble closely other *Satyridæ*" (p. 32).
>
> "As much as the coloration of the wings varies within narrow limits in different species of this genus, it is, however, in general similar" (p. 26).
>
> "In the Neotropic genus *Phoraspis*, Serv., the forms with a light longitudinal fillet on the indistinctly ribbed elytra and with pronotum cleared to a glassy appearance on the sides, between which the head appears, resemble somewhat the 'Lampyridæ'" (p. 7).

Seitz is made to say that a nauseous odour is emitted by a certain butterfly (*Eueides*) "only when danger threatens or on direct insult." He is thus made to describe the evidence on which this conclusion was based: "I approached two of these insects during copulation and smelled of them, but could perceive nothing." Such conduct is evidently regarded as not sufficiently insulting to produce the desired effect (pp. 56, 57).

Schilde is represented as saying

> "that the (mimetic) *Pieris* 'would become extinct if it were not otherwise compensatingly protected in its own garb, long before the first traces of the aping of the gaily-colored species had been teleologically selected on its white wings'" (p. 124).

The mimetic female *Pierinæ*, we are told on p. 66,

> "flutter in low flight and little exposed through the thickets visiting at most the edge of the forest, where their models suck the juices of flowers."

Haase argues that in certain butterflies transparency is even more effectual for protection than a conspicuous "warning" appearance; the metaphor in which he expresses this opinion is thus rendered on p. 98:

> "We must conclude that for protection against the obstinate enemies a 'tarn cap' is more advantageous than a 'gorgon's head.'"

We have now to inquire whether the translator possessed the requisite knowledge of the details of the subject-matter. The following examples will show that he must have been absolutely ignorant of it; and the blunders due to this cause are far more injurious than the others already treated of, and detract in a still more serious manner from the scientific value of the work. The want of technical knowledge causes many words and sentences to be rendered in a manner entirely at variance with their true meaning.

Thus the hooked hairs of certain crabs are spoken of as "angling hairs" (p. 151). The *Attidæ* are said to "suffer greatly from the persecutions of their spider-enemies" (p. 5): the author evidently stated that they suffered from the attacks of the "enemies of spiders." The "lepidopterologist" (p. 123) may well fail to recognise the familiar cyanide bottle under the description of "potassium glass" (p. 47).

Even the familiar words "Lepidoptera," "butterfly," "moth," are sometimes used in an entirely wrong sense. Thus on p. 138 we are told that "Mimicry of members of *other genera of the same subfamily* occurs not only in the Lepidoptera, but also among *Danainæ*" and several other well-known Lepidopterous sub-families. Speaking on p. 37 of a moth (*Chalcosia*), the author is made to say that "the pinned insect was more tenacious of life than any other butterfly with which I am acquainted." On p. 146 the common hawk-moth *Smerinthus ocellatus* is spoken of as a butterfly. The "empty pupal case of a butterfly," alluded to on pp. 147 and 154, should certainly be the "empty cocoon of a moth." Again, the word for butterfly is sometimes (p. 38) rendered by *Papilionidæ*. By a similar blunder, on p. 41, the genus *Papilio* is itself excluded from the *Papilionidæ*.

Instead of rendering the German descriptive terms by the corresponding English ones, the translator merely attempts a literal translation of the former. The absurd results of this procedure are so thickly spread over the book, that they form one of its worst features. Thus we are constantly told of "shaded," "secondarily shaded," and "cleared" wings, of "fillets" (*e.g.* "four orange fillet remnants," p. 7, "cellular fillets," p. 29), and of "limbal" markings. We read of the "yellow flanks" of a female Papilio (p. 93), and of "smeary" larvæ (p. 65). A "New Hollandish" genus (p. 133), the "lemon butterfly" (p. 148), and the "stem" of the aculeate abdomen (p. 134), are doubtless intelligible to an entomologist, although not the terms we should employ in this country.

I should wish, in conclusion, to express regret that Haase's painstaking and, in many respects, useful work—marred as it is by excessive arrogance, by its imperfect acquaintance with the literature of the subject, by its numerous errors, and by the rashness and frequent absurdity of its confident conclusions—should have been introduced to the English-speaking public in a form which is completely destructive of such merits as it may be fairly claimed to possess.

E. B. P.

THE ACTION OF MEDICINES.

Lectures on the Action of Medicines: being the Course of Lectures on Pharmacology and Therapeutics delivered at St. Bartholomew's Hospital during the Summer Session of 1896. By T. Lauder Brunton, M.D., D.Sc., LL.D., F.R.S., F.R.C.P., &c. 8vo. Pp. xv + 673. (London: Macmillan and Co., Ltd. New York: The Macmillan Company, 1897.)

DR. BRUNTON, in his preface to this substantial volume, writes as follows:

> "I acknowledge at once that the lectures are imperfect. They are redundant in some parts and scanty in others; they are not well adapted for the purpose of cramming, and any man who tries to pass an examination upon them alone will not be at all likely to get the maximum number of marks. But I do not think that lectures are intended for the purpose of cramming. Their use is not to supply the student with all the information he needs, but to awaken his attention, to excite his interest, to impress upon him certain points which will form a nucleus for his knowledge, and around which he may afterwards group more information."

Wise and experienced teachers will regard as a merit, what the author thus modestly admits as an imperfection. His lectures, like Sir Thomas Watson's and others that are placed among the classics of medicine, do not contain a complete statement of all that can be said on their subject; but they do excite the reader's interest, they do arrest his attention, they make him perforce reflect for himself, and they in this way truly subserve his education in the best sense of that much-abused word.

The lectures must have been delightful to listen to; every sentence bears the impress of their author's genial personality. Nothing connected with drugs and their actions is without interest to him; and he assumes, and rightly assumes, that his hearers must share his interest. His style is artistically simple and direct; allusions, illustrations, analogies, experiences, anecdotes, are introduced at every turn, and the light of his gentle humour plays effectively over many a passage. The old-fashioned *materia medica* lecture used to be regarded as the driest and dullest of the medical course: Dr. Brunton has transfigured it into one of the brightest. It is his special merit that the change has been brought about without the least sacrifice of scientific method or scientific precision; for the whole book is instinct with the spirit of modern physiology and pathology. Empirical *axiomata media* cannot yet be wholly excluded from therapeutics, but Dr. Brunton is never content with a mere induction from experience when it is possible to suggest a rational explanation. And if the suggestion is capable of being tested by experiment, the experiment is made.

> "I was once demonstrating the action of ammonia before a class here many years ago, and showed that if you held either ammonia or chloroform before the nose of a rabbit the heart stopped instantaneously. This stoppage of the heart takes place reflexly through the fifth nerve as an afferent, and through the vagus as an efferent nerve. After the lecture was over, a student came up to me and said: 'If ammonia held before the nose stops the heart, how is it that it is of use in fainting? It ought to be exceedingly bad in fainting, and yet everybody knows it is good.' Well, I simply did not know. I said: 'I think it may possibly be that it tends at the same time to cause a deep inspiration, and thus stimulates the heart indirectly.' But I was not satisfied with this explanation, and so I put the question to the test of experiment. I found the answer to be this: At the same time that you stop the heart through the vagus by ammonia or any other irritating volatile substance held before the nose, you stimulate reflexly the vasomotor centre, cause contraction of the arterioles, and raise the blood-pressure enormously."

This specimen is typical; it can be paralleled by a multitude of others, and it exemplifies at once the style and the spirit of Dr. Brunton's teaching.

The general plan of the book follows the lines of the schedule recently adopted by the Royal College of Physicians as defining the scope of an examination in pharmacology for students aspiring to their licence. Before, however, any examination had been held, a retrograde step was taken by a majority of the Fellows, and this special examination was abolished. Among the grounds alleged for so unusual a course were the supposed vagueness of the limits of the science, and the absence of appropriate text-books. It cannot be doubted that, had the present work been then accessible to students, these grounds of objection would have proved untenable. "The action of medicinal agents on the body in health and disease" forms, indeed, the essential scientific foundation for the "practical art of therapeutics" which every medical licentiate is assumed to have acquired; without this foundation he must needs be a mere empiric. The author has shown that the ascertainable facts in reference to medicinal action constitute already a coherent and orderly body of knowledge, and that future progress in rational treatment is dependent on the pursuit of the methods of scientific pharmacology in this sense of the term. He has furnished the student with an excellent guide to both facts and methods, and has thus removed the last excuse for the maintenance of mere rule-of-thumb tradition. It is to be hoped that, at no distant day, the Royal College will reconsider its last decision in the light of better knowledge and broader conceptions of medical education.

In accordance with the plan of the above-mentioned schedule, the actions of medicines are first considered from a physiological point of view, as they affect the various functions and systems of the body, normal or morbid. The movements of the alimentary canal and digestion; the composition of the blood, nutrition and metabolism; the heart and blood-vessels, and the circulation; disorders of the circulatory function, such as inflammation; absorption of inflammatory products; secretion and excretion; respiration; the nervous system and sleep; the sensory functions and pain; the reflex and motor activities of the nervous system; the regulation of bodily temperature and fever; specific poisons and infections; all of these are capable of being altered, modified, or controlled by medicinal agents, and the mode in which the latter exert their special action and produce their recognised effects is fully set forth.

But in many cases the practitioner has to ask himself not only what agents at his command are capable of modifying a given function in a desired way, but also what organs or functions may be affected by a given remedy administered in a particular manner. It is therefore necessary again to traverse the ground, at least in part, arranging the subject-matter under the heads of the chief medicines and therapeutic methods in ordinary use, and summarising their numerous primary and secondary actions on the body at large. The last half-dozen chapters do this clearly and succinctly. There is perforce some repetition of the earlier chapters; but the student is made to feel that not a page could be dispensed with, and the book ends long before his attention is fatigued or his interest exhausted.

It would, however, be a mistake to regard the book as good for students only: it is full of wise aphorisms and sagacious hints of the greatest value to men engaged in actual practice. There is scarcely a page from which even a practitioner of long and wide experience could not cull a suggestion, leading to the better use of his familiar tools, or to the elucidation of some old-standing puzzle. Alike to the student who is learning the subject for the first time, to the medical man in search of light and leading in the perplexities of treatment, and to the "intelligent reader" who desires to appreciate the advances made by modern medicine to a place among the sciences, we can cordially commend this fascinating work.

ORGANIC CHEMICAL MANIPULATION.

Organic Chemical Manipulation. By J. T. Hewitt, M.A., D.Sc. Pp. xi + 253. (London: Whittaker and Co., 1897.)

THIS is in some respects a useful little book, but it might easily have been made much more useful. It is divided into two parts. The first portion—102 pages—is occupied mainly with a very brief description of processes of purifying organic substances, namely, crystallisation, distillation, melting-point determination, and sublimation; and a short outline of the processes of ultimate organic analysis. A large part of the matter in this section of the book is what the student will find in almost any text-book on quantitative analysis, and might perhaps with advantage have been omitted here, and its space devoted to an extension of the matter in Part ii., and to more exact and detailed directions for carrying out the "manipulations" therein described. The second part of the book, covering 150 pages, is on the "preparation of organic substances." This, at least, is what it professes to be; but there is so much "descriptive" matter distributed throughout it, that in parts it more resembles a simple text-book on organic chemistry, with experiments thrown in. For example, after giving very fair directions for the preparation of methane from sodium acetate, and the performance of two or three experiments illustrative of its properties, the author proceeds to describe, in the true text-book style, the various other methods for the preparation of marsh gas. Thus:—

> "To obtain perfectly pure methane, zinc-methyl is decomposed by water:
>
> $$Zn(CH_3)_2 + 2H_2O = 2CH_4 + Zn(OH)_2.$$
>
> An interesting synthetical method for the formation of methane was discovered by Berthelot, who led a mixture of sulphuretted hydrogen and the vapour of carbon disulphide over red-hot copper:
>
> $$CS_2 + 2H_2S + 8Cu = CH_4 + 4Cu_2S.$$
>
> The following general methods of the formation of paraffins, *i.e.* hydrocarbons of the general formula $CuH_2n + 2$, may be mentioned."

And so on, and so on (pages 106–7).

Again, we read:

> "The aldehydes are nearly always produced by the oxidation of the corresponding primary alcohols, the process being usually carried out with potassium dichromate and sulphuric acid, *e.g.*:
>
> $$3CH_3CH_2OH + K_2Cr_2O_7 + 4H_2SO_4 = 3CH_3.CHO + K_2SO_4 + Cr_2(SO_4)_3 + 7H_2O.$$
>
> Another way is to distil a mixture of the barium or calcium salt of an acid with the corresponding formate; the following reaction then takes place:"

And so on for nearly three pages. This is all very true, and good enough of its kind; but it savours too much of the ordinary descriptive text-book, and too little of "Organic Chemical Manipulation."

Why such "manipulations" as taking the density or specific gravity of an organic liquid, or finding the optical activity of a sugar solution, should be introduced in the part of the book supposed to be devoted to the "preparation of organic substances" is not quite evident. The directions given for the preparation of the various compounds dealt with, although often very good, are not always above criticism; for example, in the preparation of ethylene the student is directed to mix 25 grams of alcohol and 150 grams of strong sulphuric acid in a flask of two or three litres capacity. Why such an enormous flask? The total volume of the mixture is barely 100 c.c., with at most another 50 c.c. to be added as the operation goes on, and to employ a flask of 20 or 30 times this capacity is simply ridiculous. Without adopting any of the well-known precautions against frothing up (which, by the way, are not hinted at), if the flask is not more than one-fourth filled with the liquid it will be amply large enough. The author then goes on to direct that the gas shall be passed through two wash-bottles in succession,

> "the first being charged with concentrated sulphuric acid to remove the vapours of alcohol and ether, the second with caustic soda solution to hold back any carbon dioxide, and towards the end of the experiment sulphur dioxide."

As water, in the form of steam, is expelled from the generating flask in considerable quantity along with the ethylene, the strong sulphuric acid in the first wash-bottle will soon become *weak* sulphuric acid, and moreover will become so hot as to render the fracture of the bottle extremely probable. If these two wash-bottles are to be used, the order should be reversed; but as a matter of fact they are quite unnecessary. If the temperature is properly regulated (for which purpose a thermometer should be passed through the cork of the generating flask, and should dip into the liquid), practically no ether is produced; and if the gas is passed through a single wash-bottle containing water, any alcohol which passes over will, for the most part, be retained there. So also will any sulphur dioxide, should the operation be pushed to such extremes that this gas is generated. Any traces of carbon dioxide which accompany the ethylene are quite immaterial, but they can if necessary be absorbed by the addition of a little caustic soda to the water in the pneumatic trough.

Lastly, after directing that the gas is to be passed through two bottles containing bromine, for the preparation of ethylene dibromide, the author adds, "the tube leading from the bromine absorption bottles must not open directly into the air, but should go into the bottom of a lime-tower which is charged from the constriction upwards with alternate layers of broken glass and soda-lime." Why not simply bubble the gas through a little caustic soda in a small beaker?

On p. 112 the following equation is given for the preparation of cuprous acetylide:—

$$C_2H_2 + CuCl + NH_3 = C_2HCu + NH_4Cl.$$

One would like to know upon whose authority this is given.

The book contains sixty-three illustrations, most of which are of the very roughest description. Fig. 36, p. 67, represents a crucible balanced in an impossible position upon a pipe-clay triangle. Again, in Fig. 60, p. 183, it is difficult to see why an exit tube is to be soldered into a hole in the tin can, instead of using the obvious two-holed cork which will carry both the safety tube and the exit tube.

In spite of these faults, however, the book will no doubt be of some use both to teachers and students of practical organic chemistry classes. N.

OUR BOOK SHELF.

Nights with an Old Gunner, and other Studies of Wild Life. By C. J. Cornish. With illustrations. Pp. xii + 307. (London: Seeley and Co., Ltd., 1897.)

MR. CORNISH'S books are widely known, and thoroughly deserve their popularity. He delights in the observation of live animals, especially birds; he describes with detail, yet with animation; and his sketches are rich in human interest. Few better books could be offered to a young fellow fond of nature, but not loving to take his pleasure too seriously. They inspire the love of close observation, and will help to make naturalists of a particularly good kind—men who will study their animals alive, and amidst natural surroundings. The illustrations are attractive, and some of the photographs from life included in this volume are acquisitions to natural history.

Critics are bound to be critical, and we shall notice the trifling matters which we would see amended in another edition. A naturalist, bred in another part of England, may be puzzled by such local words as "marrum grass," "crab grass," and "king crab." The present writer wants to know what they are, but cannot easily find out. The comparison of the shrimp and prawn (p. 87) is not exact, and we are startled to read of the hundred mouths of the sea-anemone (p. 81). A little more information might have been given about the food, and especially about the winter-food, of the beaver. This would have led to an explanation of the purpose of the dam. But Mr. Cornish does not attempt to tell all; what he tells is told so pleasantly that we long for more. L. C. M.

Untersuchungen über den Bau der Cyanophyceen und Bakterien. By A. Fischer. Pp. 132, and 3 plates. (Jena: G. Fischer, 1897.)

THIS little volume is very full of information on methods of fixing and staining, and on the results of high power observations of these minute organisms. Fischer's principal conclusions are that staining depends on physical and not chemical properties of the dyes and cell-substances, and consequently there are no such things as nuclear stains.

That the cell of the Cyanophyceæ consists of a central body clothed with a true chromatophore and devoid of a nucleus.

That neither the sulphur-bacteria nor the other schizomycetes examined contain a nucleus, and that the interpretation of bacteria as composed of a nucleus denuded of protoplast is incorrect. Also that "Die starke Färbbarkeit der Bakterien mit Kernfarbstoffen ist ein Mythus."

With regard to these and many other points concerning the structure of the bacterium-cell, it would appear probable that Bütschli—whose conclusions are especially criticised—should have something to say: and judging from certain extremely pretty preparations of *Tolypothrix* which Dr. Scott exhibited a few years ago, and from recent work by Mr. Wager on the nuclei of bacteria, it may be that Fischer's interpretation of the stained groups of chromatin-like filaments, granules, &c., as "probably reserve materials," will not be accepted as final.

In any case, the work is a most acceptable contribution to the controversy on this extremely difficult subject, and two of the three plates suggest the question why can we so rarely have English memoirs so well illustrated?

Electricity and Magnetism for Beginners. By F. W. Sanderson. Pp. ix + 244. (London: Macmillan and Co., Ltd., 1897.)

THIS little book is "intended to form a first course for boys who have already learnt the elements of mensuration, statics, dynamics, and heat"; the object being "to introduce the student to the principal laws of" electricity and magnetism, "and give him a working knowledge of the quantities involved."

This object is, on the whole, well attained, though we cannot help thinking that the book would be more valuable to beginners if it covered less ground, and dealt with the elementary portions at somewhat greater length.

The experiments described are well chosen and well arranged. It is intended that the student shall repeat them himself, and for this purpose they are admirably adapted, the apparatus required being of the simplest character. The diagrams, too, are excellent, both in execution and design.

Each chapter ends with a set of numerical examples.

Altogether, a boy who has mastered the book will possess a very creditable acquaintance with the elements of his subject. A. P. C.

Organic Chemistry for the Laboratory. By Prof. W. A. Noyes, Ph.D. Pp. xi + 257. (Easton, P.A.: Chemical Publishing Company, 1897.)

IN this attractive-looking and admirably printed work the chief practical methods of modern organic chemistry are illustrated by directions for the preparation of a large number of compounds by means of typical reactions. The various substances involved are classified according to their constitution, one chapter of the book dealing with acids, another with hydrocarbons, &c., and in all cases the chemistry of the reactions is discussed. Nearly a hundred different preparations are described, some of them of considerable difficulty; but in all cases the directions are clear and sufficient, without being unnecessarily detailed, whilst copious references to original literature are given. The book is intended to serve both for advanced students and for beginners; but, like many other works on the same subject, it is somewhat lacking in suitable experiments to illustrate the earlier portion of the lecture course from which the student derives his acquaintance with the theoretical side of the science. A. HARDEN.

The Reliquary and Illustrated Archæologist. Edited by J. Romilly Allen. New series, vol. iii. Pp. 256. (London: Bemrose and Sons, Ltd., 1897.)

THIS fine volume does credit to British archæology. It is made up of the four quarterly numbers issued this year, and is the most attractively illustrated publication that has come before us for some time. The periodical is, to quote the sub-title, "devoted to the study of the early Pagan and Christian antiquities of Great Britain; mediæval architecture and ecclesiology; th development of the arts and industries of man in the past ages; and the survivals of ancient usages and appliances in the present." The volume has thus a very comprehensive scope, and it contains articles of interest to every archæologist, numerous critical reviews, and notes on archæology and kindred subjects.

The Commercial Uses of Coal Gas. By Thomas Fletcher, F.C.S. Pp. 104. (Warington, Manchester, and London: Fletcher, Russell and Co., Limited).

GAS engineers and fitters will find this little volume, which is a supplement to one on "Coal Gas as a Fuel," worthy of attention. The book contains many notes which will be found particularly serviceable in workshop practice, and in the laboratory as well. One of the chapters "On the Use of the Blowpipe," for workshop purposes, deserves special mention. The book may be taken as a statement of the advantages of coal gas as a fuel.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Law of Divisibility.

MAY I briefly supplement my former letter by a few suggestions for the development of the above law?

(1) When δ (or a multiple) appears in N, it may be replaced by cyphers.

Thus if $\delta = 3$, for 235697 write 205007,
$= 7$, do. 200690 or 230090
$= 23$, do. 5007.

(2) Any member of the recurring period r_n may be represented by its negative complement which reaches its maximum at $\frac{1}{2}\delta$.

Thus if $\delta = 7$, period $= \pm 1, 3, 2$;
$= 11$, do. $= 1, -1$;
$= 37$, do. $= 1, 10, -11$;
$= 41$, do. $= 1, 10, 18, 16, -3$.

(3) If the final remainder be negative, its complement must be taken.

Thus if $\delta = 7, 17, 29, 41$,
and $R = -2, -14, -25, -32$,
true value $= 5, 3, 4, 9$.

(4) Final remainders may be found by repeated applications of the requisite formula.

Let $\delta = 41$,
$N = 3205175$ or 3000175
$N_1 = 5 + 70 + 18 + 30$
$= 123 = 3 + 20 + 18 = 41$,
Let $\delta = 37$,
$N = 87172$
$N_1 = 2 + 70 - 11 + 7 + 80$
$= 159 - 11 = 148 = 8 + 40 - 11 = 37$.
Let $\delta = 7$,
$N = 8638$
$N_1 = 8 + 9 + 12 - 8 = 21 = 1 + 6 = 7$.

(5) The group principle may be applied to $\delta = 99, 999, 9999$ &c., where $N_1 = a_2 + b_2 +$ &c.; $a_3 + b_3 +$ &c.; $a_4 + b_4 +$ &c. The first is a test for 11, the second for 37, the third for 101.

(6) Another method is the following:—

Let $N \div \delta + 1 = Q_1$ with remainder r_1,
$Q_1 \div \delta + 1 = Q_2$ do. r_2,
$Q_2 \div \delta + 1 = Q_3$ do. r_3,
&c. = &c.

$$\begin{aligned} \therefore N &= (\delta + 1)Q_1 + r_1 \\ &= (\delta + 1)^2 Q_2 + (\delta + 1)r_2 + r_1 \\ &= (\delta + 1)^3 Q_3 + (\delta + 1)^2 r_3 + (\delta + 1)r_2 + r_1 \\ &= \text{\&c.} \end{aligned}$$

Eliminating multiples of δ, we get, when $Q_n = 0$,

$$N_1 = r_{n-1} + r_{n-2} + \text{\&c.} + r_1.$$

If $\delta \pm a$ be used, we get

$$N_1 = a^{n-1}r_{n-1} \pm a^{n-2}r_{n-2} + \text{\&c.} \pm r_1.$$

Putting $a = 1, 2, 3$ we may deal with a wide series of primes, such as

19, 29, 59, 79, 89, 109 &c.
31, 41, 61, 71 &c.
23, 43, 53, 73, 83 &c.;

also with composites, as

119 for 17 and 7, 129 for 43 and 3,
159 for 53 and 3, 201 for 67 and 3,
301 for 43 and 7, 501 for 167 and 3, and so on.

As examples, let $\delta = 399 = 3 \times 7 \times 19$.

$$N = 8293177893$$

$$\begin{aligned} \div 400^3,\ r_1 &= 293 \\ r_2 &= 144 \\ r_3 &= 232 \\ r_4 &= 129 \end{aligned}$$

$400)\ 798 = 398$
$\quad\quad\quad\quad\quad\quad 1$
$399 = 19 \times 7 \times 3$.

Let $\delta = 299 = 13 \times 23$,
$N = 166371972$
$\div 300^4,\ r_1 + r_2 + r_3 + r_4 = 72 + 173 + 48 + 6 = 299$.
Let $\delta = 501 = 167 \times 3$
$N = 640550043$
$\div 500^4,\ 5 - 62 + 100 - 43 = 0$.

From the foregoing I have derived many simple rules not requiring division. HENRY T. BURGESS.

Tarporley, West Norwood, November 4.

A Link in the Evolution of a Certain Form of Induction Coil.

AT a time when much interest is taken in the oscillatory electric discharge and its effects, it may not be out of place to mention that a link in the evolution of the Tesla coil is to be found in a paper by Dove (Royal Academy of Sciences, Berlin, October, 1844; *Electrical Magazine*, vol. ii. p. 67). It is as follows:—The external coatings of two Leyden jars were connected together by a wire spiral. This spiral was surrounded by a secondary insulated spiral. When the jars were so charged that a spark was produced on joining their internal coatings, electricity was induced in the secondary spiral. If to this arrangement of Dove, a cistern of insulating oil be added to contain the coils, and the jars, furnished with a spark gap, be charged from an induction coil, we have one of the combinations which has given such excellent results in the hands of Tesla. In 1831 Faraday ("Experimental Researches," vol. i. § 24) arranged an experiment to discover whether the electrical discharge of a Leyden jar would produce an induced current in his induction coil; he writes: "Attempts to obtain similar effects by the use of wires conveying ordinary electricity (*i.e.* from a jar) were doubtful in results."

The combination due to Dove, is probably the earliest instance of an apparatus in which electrical oscillation in one circuit set up a definite disturbance in a neighbouring coil.

Oxford, November 8. F. J. JERVIS-SMITH.

The Leonid Meteors.

I SHOULD be glad to receive accounts of any brilliant meteors that may be observed on the nights of November 13 and 14 next, for the purpose of computing their real paths in the air. The date and time of appearance of each object should be given, together with its apparent magnitude (compared with the moon, planets or brighter stars), observed course amongst the stars in R.A. and Declination, and estimated duration of flight. Though moonlight will be strong, many observers will be on the look-out for the vanguard of the Leonids, so that should any brilliant meteors appear, they are likely to be noticed at several different stations. W. F. DENNING.

51 Brynland Avenue, Bishopston, Bristol.

Insects and Colour.

THE following incident may throw some further light on the subject brought forward by your correspondent, Mr. J. Parkin, in his letter in your issue of November 4, on "A Bee's Movements in a Room." In the year 1893, the humming-bird hawk moth was particularly common here. On one or two occasions, driving out in a little trap, with a Shetland pony, whose head-gear was ornamented with pyramidal blue rosettes, one of these beautiful insects would fly straight at one of the rosettes, and hover over it for a few seconds, though the pony was going at a trot. It would seem that in this case the colour alone was the chief attraction; the odour being insignificant. But there are, I believe, numerous other instances of insects being attracted in the first instance by colour. I may add that these insects visited chiefly the *scarlet* geraniums in my garden.

ALFRED THORNLEY.

South Leverton Vicarage, Notts., November 5.

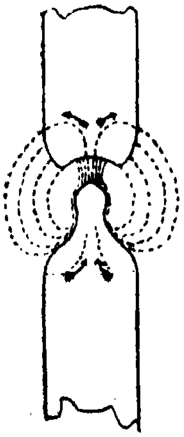
HIGH PRESSURE ELECTRICITY.[1]

THIS book is not a mere ordinary *édition de luxe*, for it is probably the most sumptuous book in connection with electricity that has ever appeared. The life-like vividness of forty-one beautifully executed photographic reproductions of electric brushes and streamers make you hear the banging of the battery of many "ten-gallon" Leyden jars; while the description of these illustrations, from the largeness of the type used, the wide spacing of the lines, the two- to three-inch margin that surrounds them, and the blank page that intervenes between every two pages of printed matter, induces a feeling of luxury in the reader, and makes him hope that the theoretical inferences will be as good as the very thick paper on which they are printed.

Lord Armstrong starts with the very striking experiment which he performed with his hydro-electric machine half a century ago. Two glasses of distilled water were placed near together, and a thread of cotton, which was coiled up in the one, had its end placed so as to dip into the other glass. Then on highly electrifying the glass of water in which the cotton was coiled negatively, and the other glass of water positively, the thread crept out of its glass into the other one, while a stream of water passed in the opposite direction.

From this he has been led to conclude that an electric current consists of two streams—a negative one in the form of a core flowing in one direction surrounded by a sort of sleeve of positive electricity flowing in the opposite direction; and he suggests, on page 24, that instead of negative and positive the names "Inward" and "Outward" would better meet his views.

He cites as an illustration of his theory the formation of the crater at the end of the positive carbon of an electric arc, and the knob at the end of the negative carbon; both of which he considers are produced by the scooping out effected by the "lines of force," which he considers follow some such path as that indicated on the accompanying figure copied from the book.



There are various reasons, however, with which Lord Armstrong is apparently unacquainted, for believing that the scooping-out theory is not correct; for example, when a thin carbon rod is put endways into an arc the rod is simply pointed like a pencil, with no appearance of any directed scooping action. Whereas, if Lord Armstrong's "lines of force" were correct, we should expect to find a cavity scooped out on one side of the carbon rod near the middle of the arc, and another on the other side near the edge. But this only happens when the carbon rod is wide, and is placed so as to split up the arc into two *distinct* arcs.

Some of the illustrations are photographic reproductions of dust figures obtained with brush discharges, while others of them were produced by causing a violent discharge from a large battery of Leyden jars to take place from a metallic disc resting on an insulated photographic plate, the disc being in some experiments positive, in others negative. In other cases two photographic plates were placed back to back with the sensitive sides outwards, and the positive and negative electrodes were placed against the two sensitised surfaces respectively.

The figure formed at the negative electrode was found to be smaller than that produced at the other, and in answer to the question "How can this be reconciled with the assumption that negative and positive action are equal?" the author remarks on page 26:—

"The answer is obvious if we admit that the negative represents suction, and the positive pressure, because in that case the negative flow will be resisted by condensation, while the positive will be helped."

And on page 44 he suggests, as a possible hypothesis, that as in a pump,

"The negative stroke, representing suction, must take the lead of the positive, and will have to draw from a neutral atmosphere. In doing so it will create a deficit in the environment which will aid inductively the impulsive energy of the positive."

On page 49 are described experiments in which negative streams were projected from an annular electrode upon a dust plate with a positive metallic ring beneath, and the author, in reference to the dust figures produced, remarks:—

"Their general appearance is strikingly like pictures of physiological cells; and what is more strange, we see them in every state of fission, from small beginnings to complete separation, and in every case the divided form displays the same internal structure as the original form from which it springs. I have already spoken of electricity as organised motion, and we have here an example of it carried to the very verge of life."

All this is probably intended only as a poetic fancy, but it reads strangely in close juxtaposition with a discussion on matter and motion, ether and atoms.

But, whatever may be the opinion of the theoretical portion of this book, whether we consider that the inward flow of negative electricity and the outward flow of positive are supported by the experiments, there can be no doubt that the illustrations form a series of valuable records of electric discharges. W. E. A.

---

[1] "Electric Movement on Air and Water, with Theoretical Inferences." By Lord Armstrong, C.B., F.R.S. Pp. vii + 55, and plates. (London: Smith, Elder and Co., 1897.)

THE REV. P. B. BRODIE, M.A., F.G.S.

IN the death of the Rev. P. B. Brodie geological science has lost one of its oldest cultivators, one who so long ago as 1834 was elected a Fellow of the Geological Society, and who was widely known for his researches on the fossil insects of the Secondary formations of England.

Mr. Brodie, who was born in 1815, was the son of an eminent lawyer, and nephew of the distinguished surgeon Sir Benjamin C. Brodie, Bart. He was educated at Emmanuel College, Cambridge, and coming under the influence of Sedgwick, a taste which he had previously manifested for geology was developed into a life-long enthusiasm for the science.

Entering the Church in 1838, the duties of his calling took him as Curate to Wylye, in Wiltshire, and for a short time to Steeple Claydon, in Buckinghamshire. Later on he became Rector of Down Hatherley, in Gloucestershire, and finally Vicar of Rowington, in Warwickshire. In all these districts he found that a rich harvest of geological facts could be gathered.

His earliest observations were on the Purbeck strata of the Vale of Wardour, and he then discovered many insect-remains, and also the Isopod which was named, by Milne-Edwards, *Archæoniscus Brodiei*. Continuing his researches in the Vale of Gloucester, on the Lias and Lower Oolites, he soon found many unrecorded fossils, and notably many remains of insects, and he thus came to publish, in 1845, his well-known "History of the Fossil Insects in the Secondary Rocks of England." An active member, for a time, of the Cotteswold Naturalists' Field Club, Mr. Brodie was later on a staunch supporter of the Warwickshire Natural History and Archæological Society, and a founder of the Warwickshire Naturalists' and Archæologists' Field Club. He was the life and soul of field-meetings, full of energy and high spirits; and at the time of his death he was President of both Warwickshire societies.

Mr. Brodie was the author of many geological papers communicated to the Geological Society, the British Association, and various scientific journals. In 1887 the Council of the Geological Society awarded to Mr. Brodie the Murchison Medal for his long and valuable geological labours; an agreeable testimony to good work achieved by one who, all his life, was a dweller in the provinces.

H. B. W.

NOTES.

THE Royal Society's medals have this year been adjudicated by the President and Council as follows:—The Copley Medal to Prof. Albert von Kölliker, Foreign Member R.S.; a Royal Medal to Prof. Andrew Russell Forsyth, F.R.S.; a Royal Medal to Lieut.-General Sir Richard Strachey, F.R.S.; the Davy Medal to Dr. John Hall Gladstone, F.R.S.; the Buchanan Medal to Sir John Simon, F.R.S. Her Majesty has signified her approval of the award of the Royal Medals.

THE following is a list of those who have been recommended by the President and Council of the Royal Society for election into the Council for the year 1898 at the anniversary meeting on November 30:—President: Lord Lister. Treasurer: Sir John Evans, K.C.B. Secretaries: Prof. Michael Foster, Prof. Arthur William Rücker. Foreign Secretary: Sir Edward Frankland, K.C.B. Other Members of the Council (the names of new Members are printed in italics): Prof. William Grylls Adams, Prof. Thomas Clifford Allbutt, *Sir Robert Stawell Ball*, *Rev. Thomas George Bonney*, *Prof. John Cleland*, Prof. Robert Bellamy Clifton, Prof. James Alfred Ewing, *Alfred Bray Kempe*, *John Newport Langley*, *Joseph Larmor*, *Prof. Nevil Story Maskelyne*, Prof. Raphael Meldola, *Prof. Edward Bagnall Poulton*, *William James Russell*, *Dukinfield Henry Scott*, Prof. Walter Frank Raphael Weldon.

WE learn from the *Times*, with regret, that in consequence of the heavy demands on his time in connection with his duties at the Natural History Museum, Sir William Flower, acting on medical advice, has reluctantly resigned the presidency of the International Congress of Zoology, which is to meet at Cambridge on August 23, 1898. Sir John Lubbock, on the unanimous invitation of the General Committee, has accepted the office, and will accordingly preside over the Congress.

WE announce with great regret the death, on October 31, of Prof. Haughton, of Trinity College, Dublin. We hope in a subsequent number to publish an obituary notice of Prof. Haughton.

IT is with much regret that we record the death of Herr Geheimrath Prof. Ernst Schering, of Göttingen, who passed away at Göttingen on November 2, at the age of sixty-four, after a long illness. Schering, besides being professor of mathematics at the University, was director of the Magnetic Department of the Observatory, the seat of Gauss' monumental researches in this branch of science.

THE Queen has conferred the Jubilee Medal upon Prof. W. R. Smith, the President of the Royal Institute of Public Health; Sir George Duffey, President of the Royal College of Physicians, Ireland; Sir William Thomson, President of the Royal College of Surgeons, Ireland; and Mr. Walter Hills, President of the Pharmaceutical Society of Great Britain.

PROF. A. A. MICHELSON, of the University of Chicago, has been elected a member of the International Committee of Weights and Measures, in the place of the late Dr. B. A. Gould.

PROF. HENRY S. PRITCHETT, of Washington University, St. Louis, has been appointed superintendent of the U.S. Coast and Geodetic Survey, as successor to General Duffield.

MR. EDGAR WORTHINGTON has been elected secretary of the Institution of Mechanical Engineers, in the place of Mr. Alfred Bache, who has retired on account of ill-health.

SIR WILLIAM GOWERS is to be entertained at dinner by the Society of Medical Phonographers on November 25. The dinner, over which Sir William Broadbent will preside, is to take place at Limmer's Hotel, and has been arranged for the purpose of congratulating Sir W. Gowers upon his honour of knighthood.

THE members of the Gerlache Antarctic expedition were entertained at Rio de Janeiro by President Moraes, and left on October 28 for Buenos Ayres, *en route* to the Antarctic region.

ON the day of his arrival in New York, Dr. Nansen was the guest of the American Geographical Society, which elected him an honorary member and conferred upon him the Cullum Geographical Medal. He was subsequently the recipient of receptions by the Swedish and Norwegian inhabitants of the city, and the National Geographical Society, Washington, and read a paper on "Some of the Scientific Results of Recent Arctic Explorations" before a special meeting of the American Philosophical Society of Philadelphia. He delivered his first public lecture at New York on November 6.

A REUTER telegram from Rome states that for some days past Vesuvius has been in active eruption, and large quantities of lava have been pouring from the crater called Atrio del Cavallo, which was opened in 1895. The lava has divided into two large streams flowing towards Vitrava and the country north of Piano del Tristre respectively, the latter current having again divided into two. The central crater is also distinctly active, throwing forth ashes and lava at frequent intervals.

ON Friday last the inaugural meeting of the recently constituted Röntgen Society took place at St. Martin's Town Hall, when Prof. Silvanus P. Thompson delivered his presidential address, particulars of which we gather as follows from the *Times*. After giving an account of the circumstances in which Prof. Röntgen made his famous discovery nearly two years ago, and referring to the antecedent investigators of whose work that discovery was a development, Prof. Thompson proceeded to make a brief review of what has been achieved with respect to X-radiations. He first discussed the improvements which have been made in appliances, such as in the construction of the tubes, in the materials used for fluorescent screens, in photographic plates, and in the methods of exciting the tubes. Turning to advances in results attained and to applications of the discovery, he said that, excepting only Lister's introduction of antiseptics and the discovery of anæsthetics, no discovery in the present century had done so much for operative surgery as that of the Röntgen rays. The first great application of the rays had been to the diagnosis of dislocations and fractures, the study of bone disease, and the detection of foreign bodies in various parts of the human frame. The localisation of foreign bodies embedded in more transparent tissue had claimed the attention of many surgeons. In this department Mr. Mackenzie Davidson had devised an ingenious apparatus by which any intelligent person could at once localise to within one-hundredth of an inch the exact position, say, of a needle in the hand or foot, the complicated geometry of oblique projection being simplified down by the instrument itself, and reduced to the application of callipers and a divided scale. As regards the physical problems presented by the rays, while there was much progress to chronicle, there was also a vast prospect opening out of problems awaiting solution. The rays had been found to possess a dissociating, or, more strictly, an ionising effect on the molecules of gases through which they passed, with the result that electrified bodies placed in an atmosphere thus affected were discharged. Further, it was now generally admitted that the rays were not themselves homogeneous—that they were of many kinds, differing in penetrative power, the quality of the mixture depending on the state of the vacuum as well as on the form of the tube and the nature of the emitting surface. The relations between the Röntgen and the kathode rays had been investigated, and important contributions to our knowledge had been made by Mr. A. A. Campbell Swinton, by M. Perrin, and by several Italian investigators. Many speculations had been put forward as to the physical nature of the rays themselves. Crookes, Tesla, and others held them to consist of flights of minute atoms or hyperatoms; on the other hand, there was an hypothesis that they were merely an extreme sort of ultra-violet light, consisting of transverse waves of excessively minute wave length. Jaumann and, apparently, Röntgen regarded them as due to longitudinal vibrations, while Sir George Stokes had put forward the view that they might be transverse waves, not in regular trains, but consisting of innumerable solitary waves. Another wide field of research was opened up by the discovery of other analogous kinds of rays. That the salts of uranium, glowworms, fireflies, and sticks of phosphorus should be able without any electrical stimulation to give out rays that could produce photographic action through substances that were opaque to every known kind of light was very suggestive, but such rays were not Röntgen rays, and obeyed different laws. It was clear, he concluded, that their little Society had an abundant field.

A SMALL marine laboratory was opened at Cullercoats on the 21st ult. by Principal Gurney, of the Durham College of Science, Newcastle-on-Tyne. It will form a most useful adjunct to the biological department of the college, as well as a centre for the investigations which have been, and are still being carried on by the Northumberland Sea Fisheries Committee. The district owes the laboratory to the public-spirited generosity of John Dent, Esq., J.P., the Vice-Chairman of the Committee, who has already made excellent contributions to the knowledge of the local condition of the in-shore waters by the trawling excursions which have been carried on since 1892—the year after the three-mile restriction was adopted. The laboratory was formally handed over to the Sea Fisheries Committee, to be worked in conjunction with the Durham College of Science, Mr. Meek being placed in charge of the scientific operations. A large company assembled, representing the Sea Fisheries Committee, the College of Science, the Natural History Society, and the County Council.

THE inaugural meeting of the seventeenth session of the Institution of Junior Engineers took place in London on Friday last, when Sir Alexander Binnie, the retiring president, presented the Institution premium to Mr. W. R. Beckton for his paper on "The Protection of Buildings from Fire," after which an address, on "Some Aspects of Railway Work," was delivered by Mr. J. A. F. Aspinall, the newly-elected president.

THE twenty-fifth anniversary meeting of the American Public Health Association was held at Philadelphia, October 26–29, Dr. Henry B. Horlbeck, of Charleston, S.C., presiding. Dr. Irving A. Watson, of Concord, N.H., who has for many years acted as secretary, resigned, and was succeeded by Dr. C. O. Probst, of Columbus, O. Among the subjects to which special attention was given were tuberculosis, yellow fever, typhoid fever, and purification of water supply. A sanitary exhibition was held in connection with the meeting.

THE *British Medical Journal* understands that Dr. Wright, the Professor of Pathology at Netley, has had an interview with the Commander-in-Chief on the subject of immunising our troops by vaccination against typhoid. Prof. Wright inoculated all the last batch of candidates for the Indian Medical Service, as well as himself and Surgeon-Major Semple. Lord Wolseley's views on the desirability of affording the protection by vaccination against typhoid to our troops are not yet announced. Any measure that gives a fair chance of mitigating the ravages of enteric among our young soldiers in India is worth a trial, provided no immediate danger or risk is incurred thereby, and no such danger attends the inoculations made in the manner devised by Prof. Wright.

AT a recent meeting of the New York Zoological Society, it was reported by the executive committee that the plans for the zoological park are practically complete, and that it is imperative that the remainder of the first 20,000*l.* of the building fund should be subscribed at once in order that the plans may be submitted to the Park Board without delay.

MR. E. E. HOWELL, of Washington, according to *Science*, has received from the U.S. Government Board of Control an order to construct a relief map of the Yellowstone National Park, for exhibition at the coming Exposition at Omaha. This model, which will be 6 by 6½ feet in dimensions, will be based upon the surveys made by the U.S. Geological Survey, and will represent the geology as well as the topography of the park. The scale will be one inch to the mile, and there will be no vertical exaggeration. The map will, it is said, be very accurate and complete, far surpassing the one made some years ago.

IT is stated that there will shortly be placed on the streets of Paris a number of electric cabs, similar to those with which Londoners are now so familiar. One of the largest Paris cab companies is said to have ordered the construction of 100 of the vehicles.

THE Guildford Natural History Society have decided to present a petition to the Commissioners of Woods and Forests, praying that Walmer Forest may be reserved as a sanctuary for wild birds, in which they, their nests, and eggs, may remain unmolested throughout the year; that it may not be let at any time for game preserving, or for any purpose inimical to bird life; and that it may remain in perpetuity as a national memorial to the great outdoor naturalist—Gilbert White of Selborne, whose observations were made in its neighbourhood.

THE *Journal of the Society of Arts* for the current week publishes a list of the Society's lecture arrangements for the session which is to open on the 17th instant, and from this we extract the following information. Before Christmas a lecture will be delivered by Prof. James Douglas, on "Progress of Metallurgy and Metal Mining in America during the last Half-Century"; and there will be one by Dr. S. Rideal, on "The Purification of Sewage by Bacteria." Among the papers that will be given after Christmas we notice the following:—"The Projection of Luminous Objects in Space," by Eric Bruce; "Aeronautics," by Captain B. Baden-Powell; "The Recent History of Papermaking," by Clayton Beadle; "The Preparation of Meat Extracts," by C. R. Valentine; "Children's Sight," by R. Brudenell Carter. Courses of Cantor Lectures are announced as follows:—"Gutta-Percha," by Dr. E. F. A. Obach; "The Thermo-Chemistry of the Bessemer Process," by Prof. W. N. Hartley; "India-Rubber," by Dr. D. Morris; "Electric Traction," by Prof. Carus Wilson. Two lectures, suitable for a juvenile audience, will be delivered on January 5 and 12, by Prof. William Ramsay, on "Fire."

THE list of lectures to be delivered at the London Institution from November to February next has been issued, and comprises, among others, discourses on "Signalling across Space," by Prof. Silvanus P. Thompson; "On the Frontier of History in Britain," by Prof. Boyd Dawkins; "The Weather Office and its Work," by Charles Harding; "Microbes—Friendly and otherwise," by Prof. W. B. Bottomley; "My Scrambles amongst the Alps," by E. Whymper; "The Position of the Mammalia in the Animal Series," by Prof. G. B. Howes; "Haunts and Habits of British Birds," by R. Kearton; "Incandescent Gas Lighting," by Prof. Vivian Lewes; "Geological Changes beneath the Ocean," by Prof. John Milne; "The First Crossing of Spitsbergen," by Sir W. Martin Conway. The Christmas course for juveniles will be by Mr. F. Enock, who will speak on "Insects at Home, at Work, and at Meals."

PARTICULARS of lectures to working men, in connection with the Royal College of Science, London, have been published. The first course is to be given by Prof. G. B. Howes, and will consist of six lectures dealing with "The Kinship of the Vertebrata." The first lecture will be delivered on Monday, November 15. Subsequent courses will be given by Prof. Le Neve Foster, on mining, and by Prof. Tilden, on chemistry.

THE Sunday Lecture Society has arranged for the delivery, before Christmas, of the following science lectures on Sunday afternoons, at 4 o'clock, in St. George's Hall, Langham Place. On November 14, "Andrée and the North Pole: a Problem of to-day," by A. Montefiore Brice; November 21, "Wireless Telegraphy," by R. Kerr; November 28, "The Land of Dragon Trees," by Dr. D. Morris; December 12, "Colour," by Dr. C. W. Kimmins; December 19, "Some Animal Co-operative Societies," by Dr. Andrew Wilson.

IT will be remembered that in 1895 the original MS. of Gilbert White's "Natural History of Selborne" was sold by Messrs. Sotheby for £294. It is now announced that the same firm will, on November 25, offer for sale an even more interesting batch of writings by the same author. These MSS. are the original letters which were sent by post by Gilbert White to Thomas Pennant between August 10, 1767, and July 8, 1773. These letters were returned to Gilbert White when he first conceived the idea of writing his famous natural history, and from them was drawn up the autograph MS. sold in 1895. The letters are all holograph but four, which are in the handwriting of an amanuensis, signed by Gilbert White, and all but three occupy four pages folio. They are additionally interesting and valuable from the fact that many of the details recorded in them were altered, omitted, or augmented in the published work. The second lot of Gilbert White MSS. is "A Garden Kalendar," dating from 1751 to 1767. It is the author's holograph manuscript, and occupies 424 pages. This has never been published, excepting the portion May 1 to November 16, 1759; it is in the form of a consecutive diary, recording the writer's almost daily operations on his own land, and notes of the results of experiments tried by him in forcing and hothouse work. All the MSS. have been continuously in the possession of the White family.

THE twentieth annual meeting of the Indian Association for the Cultivation of Science was recently held at Calcutta, and a copy of the report adopted upon that occasion is before us. In the course of the year covered by the report, lectures were delivered before the Association upon various divisions of physical and natural science. The Association does not appear, however, to be in a very flourishing condition, and it needs more financial support to put it on a satisfactory basis. In an oration characteristically Indian, the Honorary Secretary urged the necessity of national support in order to make the Institution worthy of India, and pleaded for the endowment of a Science Institute in the metropolis of India. One passage from this aspiring address reads thus:—"Whether our Association will endure to continue to be the regenerating influence for our country may still be in the region of doubt; but if the relationship of cause and effect be eternal, then I can assure you, gentlemen, that circumstanced as our country is it will have to advance, unless otherwise doomed by an eternal decree—it will have to advance, I say with all the emphasis in my power, through the regenerating influence of science and of science alone, and that, therefore, other but similar institutions will have to take the place of ours." Surely such zeal for the cultivation of science, and faith in the social influence of scientific thought, will not go unrewarded.

THE Meteorological Commission of the Cape of Good Hope have published a valuable discussion of the rainfall of Cape Colony for the ten years 1885-94, based upon the monthly and yearly averages for 278 stations, and accompanied by sixteen explanatory maps. The work has been prepared by Dr. Buchan, and has, therefore, every guarantee of scientific accuracy. We extract a few brief notes from his remarks. The annual map shows that the distribution of rainfall over South Africa to the north of the latitude of Clanwilliam (32° 10′ S.) steadily increases from west to east, the amount on the Atlantic coast falling short of 5 inches; whereas on the east coast, for some distance to the north and south of Durban, it exceeds 40 inches. The smallest mean annual rainfall is 2·45 inches at Port Nolloth; it rises above 10 inches over the eastern and southern regions and above 20 inches in certain restricted regions, including Kimberley and the Cape. In the south-east some places have a mean range above 30 inches, the largest being 38·10 inches at Kologha (lat. 32° 31′ S., long. 27° 21′ E.). The heaviest rainfalls in any year are reported from the south-west of the Colony, and the least in the north-west; at Port Nolloth the fall in the driest year does not amount to an inch. Dr. Buchan traces the causes of the very variable rainfall to the geographical distribution of pressure with the resultant winds therefrom, and to the geographical distribution of temperature.

WE are sorry to notice the report that, owing to the present condition of the sugar industry, the publication of *Timehri*, the organ of the Royal Agricultural and Commercial Society of British Guiana, is to cease with the December number. We have on many occasions drawn attention to the magazine, in the contents of which is always to be found something of interest and scientific value.

UNDER the name *Capra mengesi*, Prof. Dr. Noack, of Brunswick, has recently described a new Arabian wild goat, of which he has obtained specimens from Herr J. Menges, the well-known German traveller and collector. The wild goat of Sinai (*Capra sinaitica*) was known to extend along the mountains down the eastern side of the Red Sea, but this new species is from the Hadramaut range on the coast of the Indian Ocean, which was recently visited by the late Mr. Bent, but apparently still requires further investigation. Prof. Noack also describes a new wolf (*Canis hadramauticus*), from the same district.

Petermann's Mittheilungen contains an able paper, by Dr. Gerhardt Schott, on the currents of the Great Banks of Newfoundland. The most interesting results, obtained from discussion of an immense number of observations, are (1) confirmation of the fact that the so-called "Gulf Stream" does not exist as a warm current east of 40° W., and has no rapid movement east of 60° W.; (2) the Labrador current does not anywhere touch the United States seaboard, and has nothing to do with the "cold wall"; (3) on the bank itself there is practically no current. It appears, unfortunately for navigation, that the positions of the warm and cold streams are not liable to definite changes with the seasons, but are irregular movements difficult to account for.

DR. OTTO NORDENSKJÖLD publishes a short preliminary account of the recent Swedish expedition to Tierra del Fuego, in *Petermann's Mittheilungen*. The expedition consisted of Dr. Nordenskjöld, Herr Dusén (botanist), Dr. Ohlin (zoologist), with two assistants and four porters, and its labours have extended over the summer seasons 1895–96 and 1896–97. From the brief notice published, we gather that contributions of considerable importance to various branches of science, especially, perhaps, geology have been made, the regions explored being of peculiar importance as a connecting-link with the great Antarctic continent.

IN our issue of September 30 (vol. lvi. pp. 520 and 521) we printed a short illustrated account of "The Progress of the Steam Turbine," and many of our readers may like to know that the current issue of the *Electrical Review* contains the first instalment of a lengthy paper on the same subject, which was read a few weeks ago by the Hon. C. W. Parsons before the Institute of Marine Engineers at Stratford.

PART 7 of "Among British Birds in their Nesting Haunts, illustrated by the Camera," by Mr. O. A. J. Lee, has just come to hand. It contains ten plates, and deals with the common guillemot, mallard, razorbill, puffin, crested tit, and red-breasted merganser. The work is published by Mr. David Douglas, of Edinburgh.

A NUMBER of new editions of scientific works have lately been received. First among these publications is the third revised edition of Prof. E. Strasburger's "Kleine botanische Practicum für Anfänger" (Jena: Gustav Fischer). In the four years which have passed since the appearance of the second edition, new knowledge has been obtained and is incorporated in the present issue. The work contains 121 figures reproduced from drawings made by Dr. Strasburger, and the text likewise represents the personal observations of the author. Students of structural botany therefore will find the book a trustworthy guide.—A second enlarged edition has been published of Dr. W. Ostwald's text-book of analytical chemistry, entitled, "Die wissenschaftlichen Grundlagen der analytischen Chemie" (Leipzig: Wilhelm Engelmann). The book was reviewed at length in NATURE (vol. li. p. 482) when it first appeared, and it has now been brought up to date. The chief addition refers to electrochemical analysis. The work is not intended for beginners, but to supply adequate theoretical support to the routine work of general analytical chemistry.—Messrs. J. and A. Churchill have published the third edition of "Elements of Human Physiology" by Dr. Ernest H. Starling. The first edition of the book was reviewed in NATURE in December 1892 (vol. xlvii. p. 146), and the chief changes which it has undergone are in the account of the coagulation of the blood, and in the section on the central nervous system.—The elementary stage of the examination in magnetism and electricity, held by the Department of Science and Art, is well covered by the "Elementary Manual of Magnetism and Electricity" by Prof. Andrew Jamieson. The fourth edition, which has just been published by Messrs. Charles Griffin and Co., provides teachers of the subject with a very helpful text-book.—Messrs. Cassell and Co. have sent us a copy of "Electricity in the Service of Man" by Dr. R. Wormell, revised and enlarged by Dr. R. Mullineux Walmsley. We notice that, though the title-page is dated 1897, the preface is dated November 1893. With one or two slight exceptions, the book appears to represent the state of knowledge at the latter epoch.—A revised and enlarged edition of "A Text-book of Physics," by Prof. Edwin H. Hall and Mr. Joseph Y. Bergen, has come to us from Messrs. Henry Holt and Co., New York. The book is an admirable text-book and laboratory manual for beginners in the systematic study of physics. The course covered is that required for admission to Harvard College, where Dr. Hall is professor of physics; and it comprises the leading elementary facts and principles of physics, and quantitative laboratory work referring to them. Teachers of elementary physics in this country would do well to provide themselves with a copy of the book, for it contains numerous ingenious and instructive experiments.—The second edition of "The Practice of Massage: its Physiological Effects and Therapeutic Uses," by Mr. A. Symons Eccles, has been sent to us by Messrs. Baillière, Tindall, and Cox. The first edition was reviewed at length in NATURE of September 3, 1896 (vol. liv. pp. 411 and 412), and we need now only say that the work has been revised and altered to make room for additional matter, especially with reference to the clinical uses of massage, without increasing the bulk of the volume.—The first part of the second edition of the serial issue of Mr. Howard Saunders's "An Illustrated Manual of British Birds" has reached us from Messrs. Gurney and Jackson. This well-known work, which has undergone revision, needs no recommendation from us.

THE additions to the Zoological Society's Gardens during the past week include two Sloth Bears (*Melursus ursinus*, ♂ ♀) from India, presented by Sir Henry D. Tichborne, Bart.; a Macaque Monkey (*Macacus cynomolgus*, ♂) from Tonquin, presented by Miss Rachel Hunt; two Palm Squirrels (*Sciurus palmarum*) from India, presented by Dr. G. H. Nowell; a Long-eared Owl (*Asio otus*), British, presented by Major-General Alex. A. A. Kinlock; a Salt-water Terrapin (*Malacoclemmys terrapin*) from North America, presented by Mr. H. Arthur Clifton; five Tesselated Snakes (*Tropidonotus tesselatus*) from South-east Europe, presented by Herr Carl Hagenbeck; a Mediterranean Peregrine Falcon (*Falco pincus*), captured in the Mediterranean, presented by Captain Watson; ten Paradise Whydah Birds (*Vidua paradisea*), three Pin-tailed Whydah Birds (*Vidua principalis*), four Crimson-eared Waxbills (*Estrelda phœnicotis*), two Red-bellied Waxbills (*Estrelda rubriventris*), two Yellow-rumped Seed-eaters (*Crithagra chrysopyga*), a Singing Seed-eater (*Crithagra musica*) from West Africa, a One-wattled Cassowary (*Casuarius uniappendiculatus*) from New Guinea, two Jackass Penguins (*Spheniscus magellanicus*) from the Falkland Islands, a Black Wood-hen (*Ocydromus fuscus*) from New Zealand, deposited; a Levaillant's Darter (*Plotus levaillanti*) from West Africa, purchased.

OUR ASTRONOMICAL COLUMN.

THE COMING TOTAL ECLIPSE OF THE SUN.—We must congratulate the British Astronomical Association on the energy they have displayed with regard to the coming eclipse in India. We hear that, in addition to the three official expeditions, a fourth, but unofficial, expedition under their auspices will be sent, and that no less than twenty-six observers have come forward to take part in it. It must not be forgotten that considerable expense is attached to such undertakings, and so large a number of observers shows that the general interest taken in such an event is very considerable.

Those who wish to combine an enjoyable winter's cruise in warm climes, with a view of the eclipse thrown in, may have noticed that the Orient Liner's steamer *Orotava* is timed to leave Colombo on January 20 next, and on her homeward voyage from Australia she will be navigated with a view to being on the line of central eclipse at the time of total obscuration. Passengers can thus proceed to Colombo, and after a short stay there, allowing sufficient time to see Ceylon, return by this vessel home, seeing the eclipse on the way. Particulars can be obtained from the Company's offices in Fenchurch Avenue, E.C.

THE BINARY β 395 = 82 CETI.—Dr. T. J. J. See has found a most interesting double system in the binary β 395, which Burnham was the first to detect (1875) and the last to measure (1891·8). The object was detected with Dr. See's usual sweeping power, namely 500, but before the components could be well divided he had to employ a power of 1500. At first the system was supposed to be new, owing to the great difficulty of observing it, but a search showed that it was none other than the system mentioned above, its cordinates being

$$\alpha = 0\text{h. } 32\text{m. } 9{\cdot}9\text{s. } \delta = -25^\circ\ 18'\ 37''{\cdot}3\ (1900{\cdot}0).$$

The most striking feature of this binary is that since its last measurement the orbital motion has been so great that the whole aspect of the system is changed. Nearly one and a half revolutions have been performed since 1875, and, curiously enough, as the companion returned to the same general position in 1886, the "observers of that and the following years failed to recognise that any sensible motion had intervened."

Dr. See has calculated from all the published observations the orbit of this binary (*Astr. Nachr.*, No. 3455), and he finds it of great eccentricity and revolving in the short period of 16·9 years.

Thus 82 Ceti becomes an important system, and should be carefully watched during the next eight years. Only three other systems revolve more rapidly, namely, β 883 in 5·5 years, κ Pegasi in 11·42, and δ Equulei in 11·45 years.

TELESCOPIC SEEING.—The Lowell Observatory is not of a fixed but of a migratory nature. Like a bird which at some period of the year changes its locality for warmer climes, so this observatory is moved to a region where the air is more suited at that time for better telescopic seeing. Oscillating between Flagstaff, Arizona, and Tacubaya, Mexico, Mr. Lowell is able to take advantage of the periods of good seeing at each of these stations. Both localities satisfy the now well-known geographical and meteorological conditions, and while Flagstaff is rather too far north, bordering on the great cyclonic movement in the north temperate zone in winter, the neighbourhood of the city of Mexico is not affected by this disturbance. The latter station is not, however, found to be ideal, owing to conditions of local topography. What these conditions are will be found stated by Mr. Lowell in his discussion on the capabilities of these two stations (*The Observatory* for November, No. 259).

The well-known observer, Dawes, always used to judge the "goodness" of the night by the size of aperture that could be satisfactorily used; thus he would speak of a one-inch night, three-inch night, up to an eight-inch night, his largest aperture being of eight inches. We are now finding out how accurate this system was, for, owing chiefly to the work of Mr. Douglass, the controversy between large and small apertures seems to be a question of the wave-lengths of the air-waves. An idea of the nature of these small air-waves will be gathered from Dr. See's interesting article in the *Astronomische Nachrichten* (No. 3455), and the diagrams shown illustrate the main conditions for good and bad seeing. These waves vary in different currents from half an inch to several feet. In cases where they move in the same direction and at a great rate the seeing is very bad. With moderate-sized waves moving slowly the definition is generally very fair. Often cross-currents occur, and when fine waves move in all directions the definition is never good, but for cases of very fine seeing only very slight traces of gently moving waves can be discerned. Theoretically for the best seeing there should be no trace of movement at all. Dr. See points out, in another article in the same journal, that the scintillation of the fixed stars can be very easily explained on this wave theory, and the experiments which he has carried out tend to corroborate this view.

THE NOVEMBER METEORS.—At the latter end of this week the earth passes through that stream of meteors which gives us a yearly display on or about the 14th of this month. Mr. Denning, who is our chief authority on this subject, and whose admirable memoir on this special swarm should be carefully absorbed, tells us that the morning hours of the 14th should be more especially devoted to their observation, although watches should be commenced a day beforehand and prolonged until the 16th. It is not, however, until the year 1898 that we expect to meet the most dense parts of the swarm, but on former occasions striking displays have been witnessed a year or two previous to the chief one, and this year we hope will be no exception. Let us trust that the weather will not be so unfavourable as it was last November.

THE CONNECTION BETWEEN THE CHARACTERS OF ISOMORPHOUS SALTS AND THE ATOMIC WEIGHT OF THE METALS CONTAINED.

IN order to assist in elucidating the question of the relationship between the chemical composition of solid substances and the nature of the crystals which they are observed to form, both as regards the exterior geometrical configuration and the interior physical character of such crystals, a series of researches were commenced by the author six years ago, having for their immediate object the exact determination of the differences presented by certain well-defined series of isomorphous salts. The differences in question, due to the different nature of the interchangeable *chemical elements, belonging to the same family group*, which by their mutual replacement give rise to the series, are so small in the case of the morphological constants, that extremely refined methods of investigation are requisite in order to detect and determine them. A large amount of detached data had previously been accumulated in crystallographic literature, but a very small proportion was characterised by the requisite degree of accuracy, and no organised attempt had hitherto been made to investigate any definitely related series of crystallised compounds in a sufficiently detailed and accurate manner. The care and precision demanded will be at once apparent when it is pointed out that the use of slightly impure or imperfect crystals, or the occurrence of slight errors of orientation in grinding out of the crystals the section-plates or prisms requisite for the optical portion of the work, would be sufficient to render the results valueless for the purpose in view. In fact such sources of error have in certain cases been shown by the author during the progress of the work to have led previous observers to conclusions diametrically opposed to the truth.

It was decided to choose, as most suitable for such a study, certain series containing in their different members the three alkali metals potassium, rubidium, and cæsium, on account of the very definite relationship and considerable intervals between their atomic weights, and the extreme electro-positive nature of the group, which latter fact rendered it likely that the differences in question would be here at a maximum. These three metals belong in the strictest sense to the same family group, and their atomic weights are respectively 39, 85·2, and 132·8, the atomic weight of rubidium being thus almost exactly the mean of the values for potassium and cæsium. The particular salts chosen, on account of the general excellence of their *crystals, were the normal sulphates and selenates*, and the double sulphates and double selenates which these salts form with the sulphates and selenates of magnesium, zinc, iron, manganese, nickel, cobalt, copper, and cadmium. The work on the sulphates, double sulphates, and selenates has at length been completed and presented to the Chemical Society (*Journ. Chem. Soc.*, 1893, 337; 1894, 628; 1896, 344; 1897, 846), and the investigation of the double selenates is now in hand. The choice of the double salts has proved equally as fortunate as that of the simple salts, inasmuch as the influence of the alkali metal is found to be of a vastly preponderating character compared with that of the dyad metal, and hence the eight groups of these salts have furnished so many independent examples of the influence of the atomic weight of the alkali metal. No effort or expense has been spared to render the work absolutely trustworthy and of a final character. The goniometers and other optical instruments employed have been without exception the most accurate that could be constructed, and the observations have been more numerously repeated upon different crystals than has ever before been attempted. Moreover, great care has been bestowed upon the preparation of perfectly pure specimens of the salts, no material being accepted which did not yield absolutely satisfactory results upon both spectroscopic and ordinary gravimetric analysis. Besides goniometrical and optical investigation, the work has included exceptionally careful determinations of the relative density of the salts in the crystallised condition, in order to afford data for the calculation of the volume relationships and of the molecular optical constants. Moreover, the observations have been extended to other than the ordinary temperatures, in order that the deductions shall not be subject to the objection that they may be simply fortuitous for a particular temperature.

Before commencing the optical part of the work attention was concentrated upon devising an instrument which should enable a section-plate (slice), or a 60° prism, to be ground out of a crystal with precisely such an orientation as might be desired, with respect to the natural faces, and therefore to the morphological axes. For the whole of the optical investigation is carried out by means of such plates and prisms of known orientation, the former being requisite for the establishment of the positions of the principal optical planes, the measurement of the optic axial angle, and the study of the interference phenomena, while the latter are essential for the determination of the three refractive indices. Manifestly, therefore, the accuracy of the optical results depends primarily upon the precision with which the desired orientation of these plates and prisms is attained. Hitherto crystallographers who have investigated the optical properties of the crystals of laboratory preparations, which are so much softer and more friable than mineral crystals, have been content either to employ plates or prisms formed by suitably disposed natural faces of the crystals themselves; or, failing such, to prepare them by grinding the crystals in oil upon a ground-glass plate, the crystal being held between the finger and thumb during the process. The difficulty of thus obtaining a plane surface having the desired orientation must be at once apparent, to say nothing of the imminent risk of breaking the crystal. At the best such a method can only be approximate, and it is attended with so much that is troublesome and vexatious that the investigation of a large series of compounds, in the detailed and accurate manner which the author desired, would be impossible.

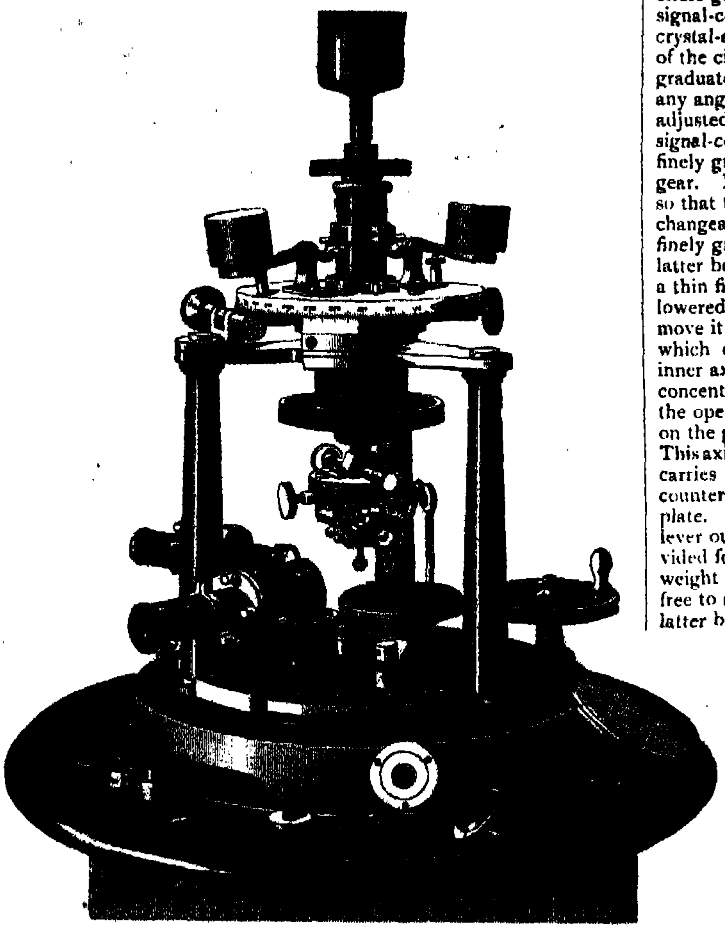


FIG. 1.

After much consideration an instrument was eventually devised, and constructed for the author by Messrs. Troughton and Simms, which achieves the desired object in a most satisfactory manner. The author has no hesitation in ascribing the success which has attended the investigation to the admirable manner in which this instrument performs its functions. More than five hundred plates and prisms have already been prepared by its aid and employed in the work; and never once, for instance, has a plate which was desired to be perpendicular to the acute bisectrix of the optic axes failed to exhibit the interference figure by convergent polarised light precisely symmetrical to the centre of the field, as it should be. Moreover, not more than half a dozen crystals have been broken *during grinding, and absolutely no* plates or prisms have required to be rejected on account of want of accuracy of orientation. Further, what was by the old method a most tedious and disagreeable part of crystallographical work, now becomes one of the most delightful and interesting.

The instrument will be found fully described in the *Transactions* of the Royal Society (1894, A, 887), but a few words here as to the principles of its construction may not be without interest. It is represented, by the kind permission of the Royal Society, in Fig. 1. It may be succinctly termed a grinding goniometer, for it combines an accurate, suspended, horizontal-circle goniometer with a grinding apparatus. The telescope and signal-collimator, together with the circle and the suspended crystal-adjusting apparatus, form the goniometer. The segments of the circular movements of the adjusting apparatus carry finely graduated silver arcs, in order to enable the crystal to be set at any angular position, with respect to any zone of faces previously adjusted parallel to the axis with the aid of the telescope and signal-collimator. The grinding apparatus consists of a small finely ground glass disc, capable of being rotated by hand driving gear. By a simple device the latter is made almost frictionless, so that the disc is rotated almost without effort. Three interchangeable discs are provided, the second being of extremely finely ground glass, and the third of polished glass, these two latter being employed for polishing; all are used lubricated with a thin film of oil. The axis of the instrument is capable of being lowered or raised, so as to bring the crystal to the grinder or remove it, by means of a large milled-headed nut near the summit, which engages with a screw thread on the upper part of the inner axis. In addition to this, however, there is another outer concentric axis capable of vertical movement, intended to enable the operator to regulate the pressure with which the crystal bears on the grinding surface, in order to avoid breaking the crystal. This axis slides in the cylindrical bore of the rotatable cone which carries the circle, and it is capable of being fully or partially counterpoised by two weighted levers carried above the circle plate. It is usually found most convenient to throw the back lever out of gear during the grinding, by raising a screw provided for the purpose on the circle plate, thus leaving half the weight of the axis to bear downwards when the front lever is free to act, and then to more or less curtail the freedom of the latter by gentle manipulation with the left hand, while the right hand is used to rotate the driving pulley of the grinding gear. After a little practice the pressure is nicely regulated almost involuntarily by the left hand in accordance with the "feel" of the grinding, rendering it most unusual to crush the crystal operated upon.

Continuous use of this instrument has proved it to be all that can be desired for use with the crystals of chemical preparations. A somewhat larger instrument has since been constructed for the author, and was described in the *Proceedings* of the Royal Society (57, 324), for use either with chemical preparations or with the harder crystals of minerals; this instrument includes an independent diamond-fed cutting apparatus, and a large selection of metallic and other grinding and polishing laps, so that plates or prisms of even the hardest natural gems can be cut and subsequently ground and polished in an equally satisfactory manner. A duplicate of this instrument is included in the National Collection in the South Kensington Museum.

A further original piece of apparatus, which the author has also found invaluable in the optical part of the work, is a spectroscopic monochromatic illuminator, a description of which will be found in the *Transactions* of the Royal Society (1894, A, 913). It has enabled the author to make observations in every case for six wave-lengths at suitable intervals in the spectrum, and has proved particularly useful inasmuch as each of the series of salts investigated has included at least one member which exhibited exceptional optical properties, generally involving crossed axial plane dispersion of the optic axes, in which instances the command of an illuminator which could be made to yield light of any desired wave-length enabled the phenomena to be studied with a completeness hitherto unattainable. In brief, the apparatus is a spectroscope with two collimators, the slit of the first being as usual for the entrance of the rays from the source of light, in the author's case the electric arc, while the slit of the second is employed as a selecting slit as in Captain Abney's well-known apparatus. The two optical tubes, however, remain fixed, while the dispersing apparatus, a single large prism of high dispersion, is made to rotate so as to bring the various parts of the spectrum across the selecting slit in turn. The selected ray issuing from the second slit is slightly diffused by a screen of finely ground glass carried in a short sliding tube in front of the slit, which is all that is required in order to flood the whole field of any of the author's observing instruments, such as goniometers, polariscopes, and microscopes, with evenly distributed monochromatic light. The accompanying illustration, Fig. 2, shows, by the kind permission of the Chemical Society, the arrangement as actually used with the gonio-spectrometer in the determination of the refractive indices.

Having thus described the difficulties of the investigation and the measures taken to overcome them, a brief outline of the results attained up to the present will now be given.

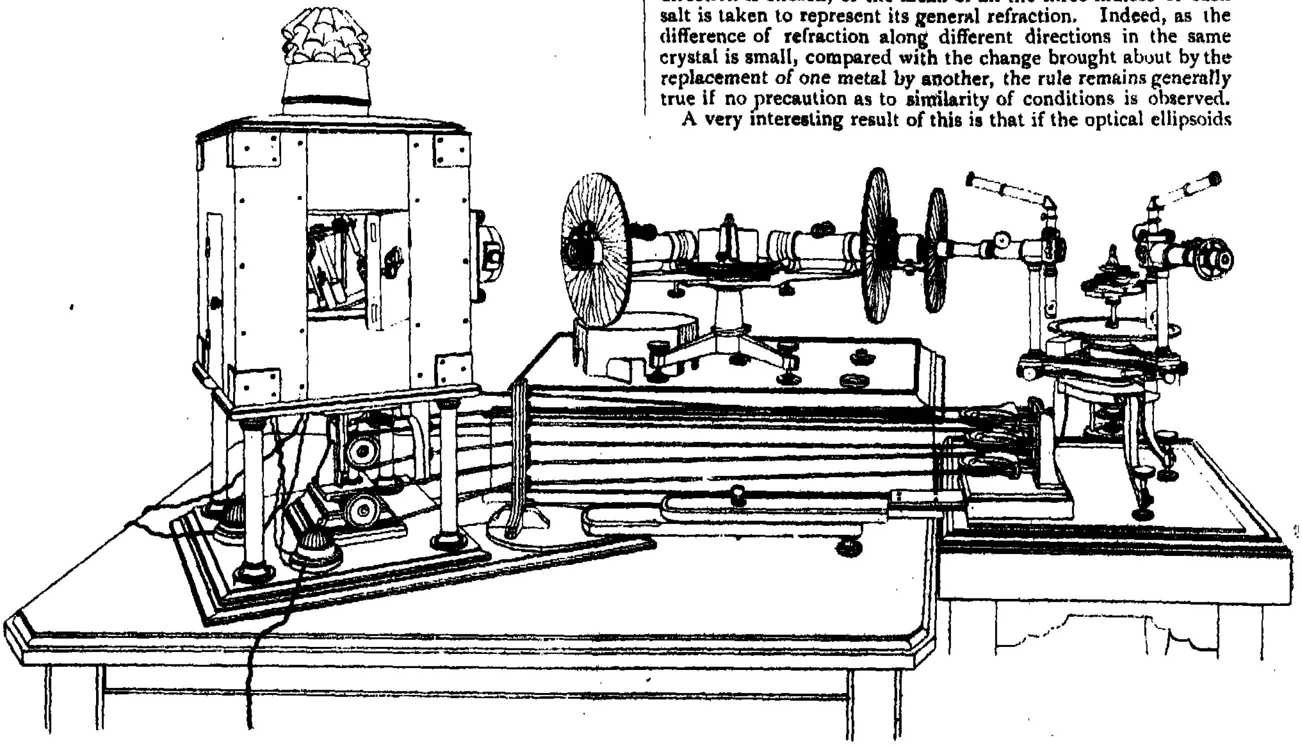

FIG. 2.

The use of the term "isomorphous" is not strictly correct, except in the cases of such series as crystallise in the primary forms of the cubic system, in which, for geometrical reasons, the interfacial angles are always identical. The normal sulphates and selenates of the three alkali metals under consideration crystallise, anhydrous, in the rhombic system, and the double salts of the series $R_2M(SO_4)_2.6H_2O$ in the monoclinic. The same planes are common to all the six simple salts, the replacement of sulphur by its family analogue selenium not effecting any change in this respect; likewise the double sulphates are characterised by planes common to their series. But corresponding interfacial angles on the different members of the same series are not identical, but differ by amounts varying from a few minutes to a couple of degrees. They are much smaller in the simple salt series than in the double salts. The result of elaborate measurements has revealed the fact that, without a single exception, the values of the angles of any rubidium salt are intermediate between those for the corresponding potassium and cæsium salts. There is consequently a progression in the angles of inclination of the crystal faces following the order of progression of the atomic weights of the alkali metals. Moreover, as a natural corollary, there is a corresponding progression in the morphological constants, the axial ratios. Still further, the influence of the nature of the metallic atoms is observed to exercise a curious effect upon the prevailing habits of the crystals. For example, the sulphates and selenates of potassium exhibit preponderating development of the brachypinacoid, the crystals usually being tabular in this direction; on the other hand the cæsium salts are characterised by the prominence of the basal plane, while the rubidium salts are distinguished by a prismatic habit due to the predominance of a brachydomal form intermediate between the two planes just mentioned.

Turning now to the optical properties, it has been found to be a rule without exception that the refractive indices of any rubidium salt are intermediate between those of the corresponding potassium and cæsium salts, and nearer to the former than to the latter, the differences being as one to three. In accordance with the biaxial character of the crystals, each salt has three refractive indices corresponding to the different degrees of facility for the transmission of light along the three rectangular directions of the axes of the optical ellipsoid. In making the comparison, the same result is obtained whether the same direction is chosen, or the mean of all the three indices of each salt is taken to represent its general refraction. Indeed, as the difference of refraction along different directions in the same crystal is small, compared with the change brought about by the replacement of one metal by another, the rule remains generally true if no precaution as to similarity of conditions is observed.

A very interesting result of this is that if the optical ellipsoids of the three rhombic sulphates or selenates are constructed, from the refraction data, about the same origin, using rectangular axial coordinates, which correspond to the mutually identical axes of morphological and optical symmetry, they are found to envelop each other; supposing the ellipsoid to be the optical indicatrix of Fletcher (the optical reference surface now universally employed), the indicatrix for the cæsium salt is the outer one, and that for the potassium salt the innermost, while that corresponding to the rubidium salt lies between the two, without touching either, but nearer to the innermost. In the double sulphate series the indicatrix likewise expands as the atomic weight of the alkali metal rises, but monoclinic symmetry only demands that one of the axes of the indicatrix shall be identical with the single symmetry axis of the system, the other two rectangular axes of the indicatrix being free to move together in the symmetry plane. The expansion of the indicatrix when potassium is replaced by rubidium or the latter by cæsium, is actually found to be accompanied by a rotation for several degrees about the symmetry axis, and the amount of this interesting rotation is more than twice as much for the latter chemical change as it is for the former.

The double refraction is also progressively affected by the replacement of potassium by rubidium and the latter by cæsium, the amount varying inversely as the atomic weight of the metal. Some very remarkable phenomena follow from this rule, owing to the fact that the initial amount of the double refraction in the potassium salt of any series or group is already very small. For a comparatively slight diminution is sufficient to bring it to zero, and even to go further and reverse its sign. As the three refractive indices of any salt are not equidistant from each other in value, and are affected to different extents by the same chemical change, they never in either the rubidium or cæsium salts become reduced to absolute identity at the same time, but become equal in pairs for specific wave-lengths of light and degrees of temperature. When this occurs the crystal becomes for that wave-length and temperature temporarily uniaxial in its optical comportment. The particular salt in which this occurs varies in the different series. In the sulphates it is the rubidium salt, in the selenates the cæsium salt, both at temperatures slightly elevated above the ordinary; in the double sulphates it occurs in cæsium magnesium sulphate and at the ordinary temperature for blue light, while in the other groups of this series the progression never quite reaches the state of equality of two indices. It will be evident that the distribution of the directions corresponding to the α, β and γ indices, and also the optic axial phenomena in convergent polarised light, vary in the three salts of each series or group to a quite extraordinary extent; so much so that without the discovery of this rule, which affords the key to them, the vagaries must have been incomprehensible. For whenever two indices become identical the third is also very nearly so, and consequently the slightest change of wave-length or temperature brings about most drastic changes in the optical phenomena dependent upon the mutual relations of the three. The most striking case is that of cæsium selenate. At the ordinary temperature the sign of double refraction and disposition of the optic axes are already reversed from what they were in potassium and rubidium selenates, and the three indices are so nearly identical that a section plate a centimetre thick is necessary to produce an interference figure in convergent polarised light. On heating gradually to 250°, the sign of double refraction changes twice over, and the optic axes move so rapidly that their acute bisectrix occupies the direction of each of the three morphological axes in turn. That these remarkable phenomena are precisely what are demanded by the rule of progression above enunciated, given the initial optical conditions of the potassium salt, is perhaps the most striking proof of the validity of the rule.

It may be here mentioned that double sulphates of potassium and manganese, and potassium and cadmium, containing six molecules of water, have not yet been obtained, although the corresponding rubidium and cæsium salts are readily formed; yet from the above rule, and others which have been indicated for the other properties, the author has been able to predict the morphological and optical constants which these salts will probably exhibit if ever they are obtained.

The determination of the densities of the crystallised salts has enabled the molecular optical constants to be calculated, with the aid of the formulæ of Lorenz and of Gladstone and Dale. It has been found that they exhibit a similar progressive increase following the increase in the atomic weight of the alkali metal, and that the increase is always greater when cæsium replaces rubidium than when the latter replaces potassium. The molecular refraction for the crystallised state of the sulphates and selenates was also compared with that for the state of solution in water, specific determinations of the density and refraction of highly concentrated solutions of known strength being made for the purpose. It was found that while the values for the two states are approximately the same, there are slight differences, due to the change of state, which observe a distinct progression; for they vary directly as the specific refractive energy and inversely as the atomic weight of the alkali metal. In both series the refraction equivalent of the potassium salt rises by 2½ per cent. when the salt is dissolved in water, and that of the rubidium salt by 1 per cent., while that of the cæsium salt decreases by ½ per cent. This interesting order of the differences clearly demonstrates the quantitative influence of the nature of the alkali metal upon even the smallest details of the physical properties; and the fact that the sign of the differences passes during the progress from positive to negative, indicates the substantial accuracy of the principle enunciated by Dr. Gladstone in 1868 that "the refraction equivalent of a solution is the sum of the refraction equivalents of the solvent and the substance dissolved," by the application of which principle the calculations for the state of solution were made.

The molecular volumes of the members of each series likewise exhibit the order of the atomic weights of the alkali metals, but the progression again proceeds more rapidly than in simple arithmetical proportion to the latter. A point of particular interest was elicited with respect to the volumes of the double sulphates, which throws a strong light upon the nature of those salts. It was found that the volume of the alkali sulphate is the same in the double salt as it is for the simple salt itself, that is to say, the simple alkali sulphate enters into the structure of the double salt without suffering any contraction in volume. This fact, contrasted with the very large contraction which accompanies the chemical union of the elementary constituents of the simple sulphates, negatives the possibility of chemical combination of the molecular constituents of the double salts. This, together with other facts which the investigation has brought to light, has led to the important conclusion that the composition of these double salts is simply a result of the aggregation of the molecular constituents in a particular type of homogeneous structure, in which they find stablest equilibrium, the very nature of this structure ensuring that the component simple molecules are always present in the same, the observed, proportion. The elucidation and definition of all the possible types of homogeneous structures have recently been elaborately worked out by Federow on the continent, and Barlow in this country, and the precise correspondence between the possible types of homogeneous structures and the observed varieties of crystal symmetry is now established beyond all doubt. The author has been able to indicate, moreover, the particular member of Barlow's classification corresponding to both the simple and double salt series.

The conclusion just referred to, regarding the nature of the double sulphates, taken in connection with other facts which the author has established, leads to a further one of a still more far-reaching character, namely, that the units of a homogeneous crystal structure are the simple chemical molecules themselves, and that the current assumption that the crystal unit is a more or less complex aggregation of chemical molecules is quite unnecessary and in general erroneous. This conclusion is further strongly supported by some recent work of Fock, on the solubilities of mixed crystals, based upon the theory of solid solutions.

Before leaving this interesting subject it should be mentioned that a method has been found, by combining the molecular volume with the morphological axial ratios, of determining the relative distances apart of the centres of contiguous chemical molecules of the sulphates and selenates, and of contiguous groups of the eight component chemical molecules of the double sulphates, each such group corresponding to the generic formula $R_2SO_4.MSO_4.6H_2O$. A comparison of these "distance ratios" shows that the replacement of potassium by rubidium, and of the latter by cæsium, is accompanied by a progressive increase in the separation of the structural units or groups of units in every direction, corresponding to the progress of the atomic weight of the alkali metal, and that the latter replacement always gives rise to a greater extension of the structure than the former.

In conclusion, the net result of the investigation has been to show that the whole of the morphological and physical properties of the crystals of each of these isomorphous series exhibit progressive variations, which follow the order of progression of the atomic weights of the alkali metals which the salts contain. Hence it may be said that these variations are functions of the atomic weight of the alkali metal, and it has been shown that the function is usually one which involves higher powers than the first. Of course atomic weight is only one of the numerous properties of an element, but it is doubtless the most convenient reference constant that could be chosen to express fundamentally the difference in the essential nature of the atoms of different elements. It is this difference in essential nature which gives rise to the rules which have been brought to light by the investigation; and the author desires to make it quite clear that atomic weight is merely employed as the basis of reference because it is the aptest expression of such difference, and not because of any virtue in atomic weight *per se*. The fact that the rules are equally applicable to series so widely different as the rhombic sulphates and selenates and the monoclinic double salts, appears to indicate their application to isomorphous series *in general. Hence the author concluded his last communication to the Chemical Society in the following words:* "The difference in the nature of the elements of the same family group which is manifested in their regularly varying atomic weights, is also expressed in the similarly regular variation of the characters of the crystals of an isomorphous series of salts of which these elements are the interchangeable constituents."

A. E. TUTTON.

THE JACKSON-HARMSWORTH ARCTIC EXPEDITION.

THE first meeting of the present session of the Royal Geographical Society took place at the Queen's Hall, Langham Place, on Monday night last, when Mr. Frederick G. Jackson lectured on the expedition led by himself to the Arctic regions. For the following abridged account of the lecture we are indebted to the *Times*:—

It was in August 1873 that the land afterwards known as Franz Josef Land was first accidentally discovered by the Austro-Hungarian expedition, under the leadership of Weyprecht and Payer. The following spring Payer made three journeys up and in the neighbourhood of what he then named Austria Sound. Arctic authorities advocated the route to the north suggested by Payer's impression that there was land still further to the north in and beyond the eighty-third degree, and land to the north-west reaching almost as far, and it was on Payer's observations that Mr. Jackson formulated his plans in the latter end of 1892. Unfortunately his expectations were fated to disappointment by the non-extension of the land to the north. His plans embraced not only an advance in a northerly direction, but the mapping-in of the coast-lines of Franz Josef Land, a thorough examination of that country, in taking scientific observations, and making collections generally. Those plans they had been able to carry out; and scientific observations had been carried on uninterruptedly for three years. They had also practically completed the map of Franz Josef Land, and settled the Gillis Land question. For some time the sinews of war were conspicuous by their absence, and little encouragement was given, but eventually Mr. Alfred Harmsworth generously offered to provide the necessary funds for the proposed expedition. They left the Thames on July 12, 1894, in the steam yacht *Windward*, calling at Archangel. Then they proceeded east, skirting the northern shores of Kolguev Island to Kharborova, a Samoyed settlement on the Yugor Straits, to take on board their thirty dogs and some fresh reindeer meat. They then steamed north through the Barents Sea, making for Bell Island, Franz Josef Land. The mass of islands of which Franz Josef Land was comprised consisted of high glacier-land rising to 2000 feet, covered with an ice-cap some hundreds of feet in thickness, and fronted along the shore by high perpendicular glacier faces from 30 feet to 80 feet in height. At rare intervals high black basaltic rocks jutted out of the ice near the shore, forming the only conspicuous landmarks. In front of these rocks the broken-down débris from the cliffs had formed a plateau, or shore, upon which a certain amount of stunted Arctic vegetation existed. Here might be found a few poppies, saxifrages, mosses, lichens, &c. Everywhere else, with the exception of a few low islands, the ice-sheet overran everything. Thick mists generally overhung this land; violent gales were frequent, combined with heavily falling and driving snow. Finding no suitable site for their hut, they returned to Cape Flora, a high basaltic cape 1400 feet high, beneath which they pitched their camp, as being the most favourable spot they had yet seen, one of the strongest inducements being the presence of a large loomery there in the high rocks, and the known presence of bears and walruses throughout the year. This they reached on September 8. They at once set to work to shoot bears and walruses for the winter, and to put up their log hut, which was named "Elmwood," and to make themselves as comfortable as circumstances would allow. On the return of the sun, about the middle of February, they got ready to start, and on March 9 Mr. Armitage and he took a preliminary journey with the object of making a depôt of provisions to the north and of ascertaining the character of the travelling in that direction. In the beginning of April they got under way with three ponies and a number of sledges, being accompanied for the first week by Dr. Koettlitz and young Hayward with one pony and sledges. Soon after rounding Dundee Point they discovered that the existing maps were not quite in accordance with fact. To the northward lay floe ice where land had been mapped in; and it was not till they reached the latitude of Point Arthur that they could discern land to the westward. To the south-west appeared open ocean. The weather now became very bad, and they were frequently confined to their tent for days together. Constant gales and driving snow impeded their advance, and the floe ice itself became very unstable with water in the deeper layers of the snow, so that they were frequently wading about in slush above their knees. They, however, pushed on. Richthofen Peak could nowhere be discerned, and no hill worthy of the name of mountain could be seen in any direction, although they were within half a mile of its supposed site. On April 30 they rounded Cape Fisher, and to the north appeared a low island, which in the distance had rather a volcanic appearance, owing to a cup-shaped elevation upon it. On May 1 they rounded Cape M'Clintock, a low weathered cape of columnar basalt, projecting out of the ice-clad land behind. A striking feature of this rock was a pillar of columnar basalt standing up in front of it. Thus it was in April 1895 that they discovered the Queen Victoria Sea, which he named after her Majesty. They reached a point 81° 20′ N. They carefully mapped in the whole coast-line, although the weather was exceedingly unsuitable for taking bearings. On May 4 they started back in a strong wind, dense mist, and driving snow, returning by the same route as they had come up. The difficulties of the floes daily increased. They had constantly to haul the ponies out of the snow morasses with ropes round their necks. They would then go for a few yards further and would flounder in again. They frequently had to take the sledges on themselves, leading the ponies through especially bad places, and had to go over the same ground thirteen times to effect this. On their return journey they got a view of the land to the north-west, which appeared to consist of islands. They returned again round the cape that he had named Cape Richthofen, thus giving themselves an opportunity of discovering the whereabouts of Richthofen Peak, if such existed; but they again failed to see any sign of such a hill in any direction. On May 12 they reached their hut at Cape Flora, getting the ponies back in the nick of time. After their return they were busy with botanical, geological, and other examinations, and in fitting up their whaleboat, the *Mary Harmsworth*, for a journey round the south-west coast as soon as the *Windward* should break loose from her winter quarters and depart for home. This she did on July 3, after being cut out of the ice. To the southward there appeared to be little ice, and from an altitude of over 1400 feet little more than open sea could be discerned. The other expeditions made by Mr. Jackson during his stay were described, and the lecturer concluded by saying that, so far from viewing Franz Josef Land as a favourable route to the Pole, his experiences now led him to believe it to be one of the worst; and although he had, in common with other Arctic explorers, the greatest desire to stand upon that mathematical point, still he had no sympathy with an attempt to reach the Pole as a mere athletic feat alone, but considered that geographical and other scientific work should always be included in the plan.

REPORT ON TECHNOLOGICAL EXAMINATIONS.

THE report on the work of the Examinations Department of the City and Guilds of London Institute for the session 1896-97 has just reached us, and is as usual a very business-like and interesting publication. We make a few extracts from it.

There has been a marked development in the work of the Examinations Department of the Institute during the past Session, as shown not only in the larger number of classes in Technology registered by the Institute, but also in the increase in the number of students in attendance at such classes, and of candidates for examination. This development is due to the further provision of facilities for technical instruction, and also to the fuller recognition of its value and importance.

The report before us shows that the Institute has endeavoured in various ways to assist this forward movement

Since the Technological Examinations were first undertaken by the Institute, the organisation of technical instruction has been greatly promoted by the Educational Committees of County Councils, with which the Institute has established close relations; and many of the improvements, which have been introduced into its schemes of instruction and examination, have been due to the suggestions of the organising secretaries of those committees.

In London, through its representation on the Technical Education Board of the London County Council and on the London Polytechnic Council, the Institute has taken a large share in the direction and organisation of the educational work of the Polytechnic Institutions; and in accordance with the original scheme of the Charity Commissioners for the administration of those bodies, the examinations of the Institute have been generally adopted, and the instruction given in those Institutions, although in no way unduly subordinated to examination influences, has been legitimately, and, it is believed, usefully, directed by the Institute's requirements.

During the session under review the number of students in attendance at the classes registered by the Institute was 32,566, as against 29,494 in the previous year, and the number of candidates' papers examined was 12,868, as against 12,099.

To enable the Institute to adapt its schemes of instruction to local needs and to the changing requirements of different trades, and to make its examinations a true test of the technical knowledge and ability of the artisan students who have been trained in its registered classes, frequent changes are made in its syllabuses of instruction, and tests of workmanship, wherever practicable, are made a part of the examination. Several alterations have been made in the programme of instruction and examination for the session 1897-98, to some of which we draw attention. Thus, in the syllabuses of textile subjects, important changes have been introduced.

Reference was made in last year's report to a discussion by a committee of experts in Lancashire of the conditions of examination in cotton weaving. The report of that committee was received by the Institute early in the session, and subsequently a conference was held in London of representatives of the Institute, the Institute's examiners and inspector, and delegates from the Technical Instruction Committee of the Manchester County Council. As a result of that conference, it was proposed that a new syllabus should be prepared in several of the weaving subjects to cover a period of three years, and that the full certificate should be granted to those students only who complete the three years' course of study. It was also considered advisable that candidates, before entering upon their first year's course of technical instruction, should pass a preliminary examination in the subjects of arithmetic, drawing, and elementary physics, in their special application to the technology of spinning and weaving. The representatives of the Union of Lancashire and Cheshire Institutes, having undertaken to prepare and submit for approval to the Committee of the Institute a syllabus of instruction for this preliminary examination, the Institute decided, after carefully considering the syllabus, to accept the certificate of the Union in lieu of the certificates of the Science and Art Department, previously required to qualify for a full technological certificate. New syllabuses were accordingly prepared in cotton spinning and weaving, in wool and worsted spinning and weaving, and also in jute spinning and weaving; and these syllabuses, after being modified by different experts to whom they were submitted, were finally adopted by the Institute, and have been inserted in the Programme. To obtain a certificate in the ordinary grade of either branch of calico or cloth manufacture, it will now be necessary that the student, unless specially exempted, should go through a two years' course of study and pass an examination at the end of each year's work.

In the subject of iron and steel manufacture, a new syllabus has been written; and with the view of adapting the examination to the requirements of students working in different parts of the country, a large number of questions will be given, covering the different sections into which the syllabus has been divided, and candidates will be at liberty to select those questions bearing upon the practice of the trade in the district in which they work.

It has been thought desirable to limit the scope of the examination in the electro-metallurgy to the principles underlying the electro-deposition of metals, and in order to bring the instruction into closer touch with the requirements of students engaged in the manufacture of electro-plated goods, the syllabus of examination has been modified, and the title of the subject has been changed into that of "Electro-Plating and Deposition."

The syllabus in mine surveying has been re-written with the view of making the instruction and examination more distinctly technical than hitherto. Questions will be set involving a knowledge of logarithms and trigonometry, and of the application of trigonometry to problems in mine surveying; but the questions in pure mathematics, which previously formed a part of the examination, will be omitted.

The report, in addition to giving particulars as to the various examinations which took place in connection with the session, contains extracts from statements made by the examiners concerning the general character of the work examined, which should prove useful to both teachers and students.

EXPERIMENTAL MORPHOLOGY.[1]

IN looking at the progress which has been made in the study of plant morphology, I have been as much impressed with the different attitudes of mind toward the subject during the past 150 years as by the advance which has taken place in methods of study, as well as the important acquisitions to botanical science. These different view points have coincided to some extent with distinct periods of time. What Sachs in his "History of Botany" calls the "new morphology" was ushered in near the middle of the present century by von Mohl's researches in anatomy, by Naegeli's investigations of the cell, and Schleiden's history of the development of the flower. The leading idea in the study of morphology during this period was the inductive method for the purpose of discerning fundamental principles and laws, not simply the establishment of individual facts, which was especially characteristic of the earlier period when the dogma of the constancy of species prevailed.

The work of the "herbalists" had paved the way for the more logical study of plant members by increasing a knowledge of species, though their work speedily degenerated into mere collections of material and tabulations of species with inadequate descriptions. Later the advocates of metamorphosis and spiral growth had given an impetus more to the study of nature, though diluted with much poetry and too largely subservient to the imagination, and to preconceived or idealistic notions.

But it was reserved for Hoffmeister (1859), whose work followed within three decades of the beginnings of this period, to add to the inductive method of research, as now laid down, the comparative method; and extending his researches down into the Pteridophyta and Bryophyta, he not only established for these groups facts in sexuality which Camerarius and Robert Brown had done for the Spermatophyta, but he did it in a far superior manner. He thus laid the foundation for our present conceptions of the comparative morphology of plants. Naegeli's investigations of the cell had emphasised the importance of its study in development, and now the relation of cell growth to the form of plant members was carried to a high degree, and it was shown how dependent the form of the plant was on the growth of the apical cell in the Pteridophyta and Bryophyta, though later researches have modified this view; and how necessary a knowledge of the sequence of cell division was to an understanding of homologies and relationships. Thus in developmental and comparative studies, morphology has been placed on a broader and more natural basis, and the homologies and relationships of organs between the lower and higher plants are better understood.

But the growth of comparative morphology has been accompanied by the interpretation of structures usually from a teleological standpoint, and in many cases with the innate propensity of the mind to look at nature in the light of the old idealistic theories of metamorphosis.

I wish now to inquire if we have not recently entered upon a new period in our study of comparative morphology. There are many important questions which comparative studies of development under natural or normal conditions alone, cannot afford a sufficient number of data. We are constantly confronted with the problems of the interpretation of structure and form, not only as to how it stands in relation to structures in other plants, which we deal with in comparative morphology, but the meaning of the structure or form itself, and in relation to the other structures of the organism, in relation to the environment, and in relation to the past. This must be met by an inquiry on our part as to why the structure or form is what it is, and what are the conditions which influence it. This we are accustomed to do by *experiment*, and it begins to appear that our final judgments upon many questions of morphology, especially those which relate to variation, homology, &c., must be formed after the evidence is obtained in this higher trial court, that of *experimental morphology*. While experimental morphology as a designation of one branch of research in plants, or as a distinct and important field of study, is not yet fully taken cognisance of by botanists, we have only to consult our recent literature to find evidence that this great and little explored field has already been entered upon.

---

[1] Address delivered before Section G (Botany) of the American Association for the Advancement of Science, at Detroit, by Prof. G. F. Atkinson. (Numerous bibliographical references were given in the course of the address, but these have been omitted.)

Experimental methods of research in the study of plants have been in vogue for some time, but chiefly by plant physiologists and largely from the standpoint of the physical and chemical activities of the plant, as well as those phases of nutrition and irritability, and of histologic structure, which relate largely to the life processes of the plant, and in which the physiologist is therefore mainly interested. In recent years there has been a tendency in physiological research to limit the special scope of these investigations to those subjects of a physical and chemical nature. At the same time the study of the structure and behaviour of protoplasm is coming to be regarded as a morphological one, and while experimental methods of research applied to the morphology of protoplasm and the cell is comparatively new, there is already a considerable literature on the subject even upon the side of plant organisms. While certain of the phenomena of irritability and growth are closely related to the physics of plant life, they are essentially morphologic; and it is here especially that we have a voluminous literature based strictly on the inductions gained by experimentation, and for which we have chiefly to thank the physiologist.

If we were to write the full history of experimental morphology in its broadest aspect, we could not omit these important experimental researches on the lower plants in determining the ontogeny of polymorphic species of algæ and fungi which were so ably begun by De Bary, Tulasne, Pringsheim, and others, and carried on by a host of European and American botanists. The tone which these investigations gave to taxonomic botany has been felt in the study of the higher plants, by using to some extent the opportunities at botanic gardens where plants of a group may be grown under similar conditions for comparison, and in the establishment of alpine, subalpine and tropical stations for the purpose of studying the influence of climate on the form and variations of plants, and in studying the effect of varying external conditions.

While experimental morphology in its broadest sense also includes in its domain cellular morphology, and the changes resulting from the directive or taxic forces accompanying growth, it is not these phases of morphology with which I wish to deal here.

The question is rather that of experimental morphology as applied to the interpretation of the modes of progress followed by members and organs in attaining their morphologic individuality, in the tracing of homologies, in the relation of members associated by antagonistic or correlative forces, the dependence of diversity of function in homologous members on external and internal forces, as well as the causes which determine the character of certain paternal or maternal structures. I shall deal more especially with the experimental evidence touching the relation of the members of the plant which has been represented under the concept of the leaf, as expressed in the metamorphosis theory of the idealistic morphology. The poetry and mystery of the plant world, which was so beautifully set forth in the writings of Goethe and A. Braun, are interesting and entrancing, and poetic communication with nature is elevating to our ethical and spiritual natures. But fancy or poetry cannot guide us safely to the court of inquiry. We must sometimes lay these instincts aside and deal with nature in a cold, experimental, calculating spirit.

The beginnings of experimental morphology were made about one century ago, when Knight, celebrated also for the impulse which he gave to experimental physiology, performed some very simple experiments on the potato plant. The underground shoots and tubers had been called roots until Hunter pointed out the fact that they were similar to stems. Knight tested the matter by experiment, and demonstrated that the tubers and underground stems could be made to grow into aerial leafy shoots. This he regarded as indicating a compensation of growth, and he thought, further, that a compensation of growth could be shown to exist between the production of tubers and flowers on the potato plant. He reasoned that by the prevention of the development of the tubers the plant might be made to bloom. An early sort of potato was selected, one which rarely or never set flowers, and the shoots were potted with the earth well heaped up into a mound around the end of the shoot. When growth was well started, the soil was washed away from the shoot and the upper part of the roots, so that the plant was only connected with the soil by the roots. The tubers were prevented from growing, and numbers of flowers were formed. This result he also looked upon as indicating a compensation of growth between the flowers and tubers.

While we recognise Knight's experiments as of great importance, yet he erred in his interpretation of the results of this supposed correlation between the tubers and flowers, as Vöchting (1887, 1895) has shown. By repeating Knight's experiment, and also by growing shoots so that tubers would be prevented from developing, while at the same time the roots would be protected, flowers were obtained in the first case, while they were not in the second; so that the compensation of growth, or correlation of growth, here exists between the vegetative portion of the plant and the flowers, instead of between the production of tubers and flowers, as Knight supposed.

The theory of metamorphosis as expressed by Goethe and A. Braun, and applied to to the leaf, regarded the leaf as a *concept* or *idea*. As Goebel points out, Braun did not look upon any one form as the typical one, which through transformation had developed the various leaf forms; but each one represented a wave in the march of the successive billows of a metamorphosis, the shoot manifesting successive repetitions or renewals of growth each season, presenting in order the "niederblätter, laubblätter, hochblätter, kelchblätter, blumenblätter, staubblätter, fruchtblätter." Though it had been since suggested from time to time, as Goebel remarks, that the foliage leaf must be regarded as the original one from which all the other forms had arisen (at that time Goebel did not think this the correct view). No research, he says, had been carried on, not even in a single case, to determine this point. Goebel plainly showed, in the case of *Prunus padus*, that axillary buds, which under normal conditions were formed one year with several bud scales, could be made by artificial treatment to develop during the first year. This he accomplished by removing all the leaves from small trees in April, and in some cases also cutting away the terminal shoot. In these cases the axillary shoots, instead of developing buds which remained dormant for one year, as in normal cases, at once began to grow and developed well-formed shoots. Instead of the usual number of bud scales, there were first two stipule-like outgrowths, and then fully expanded leaves were formed; so that in this case, he says, the metamorphosis of the leaf to bud scales was prevented. For this relation of bud scales to foliage leaves, Goebel proposed the term "correlation of growth." In the case of *Vicia faba*, removal of the lamina of the leaf of seedlings, when it was very young, caused the stipules to attain a large size, and to perform the function of the assimilating leaf. He points out that experimentation aids us in interpreting certain morphological phenomena which otherwise might remain obscure. He cites the occasional occurrence ("Moquin-Tandon") in the open of enlarged stipules of this plant, which his experiment aids in interpreting. In the case of *Lathyrus aphaca*, the stipules are large and leaf-like, while the part which corresponds to the lamina of the leaf is in the form of a tendril, the correlation processes here having brought about the enlargement of the stipules as the lamina of the leaf became adapted to another function. Kronfeld repeated some of Goebel's experiments, obtaining the same results, and extended them to other plants (*Pirus malus* and *Pisum sativum*), while negative results attended some other experiments. Hildebrand, in some experiments on seedlings and cuttings, found that external influences affected the leaves, and in some cases, where the cotyledons were cut, foliage leaves appeared in place of the usual bud scales. In *Oxalis rubella*, removal of the foliage leaf, which appears after the cotyledons, caused the first of the bulb scales, which normally appear following the foliage leaf, to expand into a foliage leaf.

In some experiments on the influence of light on the form of the leaves, Goebel has obtained some interesting results. Plants of *Campanula rotundifolia* were used. In this species the lower leaves are petioled and possess broadly-expanded, heart-shaped laminæ, while the upper leaves are narrow and sessile, with intergrading forms. Plants in different stages of growth were placed in a poorly lighted room. Young plants which had only the round leaves, under these conditions continued to develop only this form of leaf, while older plants which had both kinds of leaves when the experiment was started, now developed on the new growth of the shoot the round-leaved form. In the case of plants on which the flower shoot had already developed, side shoots with the round leaves were formed.

Excluding the possibility of other conditions having an influence here, the changes in the form of the leaves have been shown to be due to a varying intensity of light. The situation of the plants in the open favour this view, since the leaves near the ground in these places are not so well lighted as the leaves higher up on the stem. In this case the effect of dampness is not taken into account by the experimenter, and since dampness does have an influence on the size of the leaf, it would seem that it might be at least one of the factors here. An attempt was now made to prevent the development of the round leaves on the young seedlings. For this purpose the plants were kept under the influence of strong and continuous lighting. The round leaves were nevertheless developed in the early stage, an indication that this form of the leaf on the seedling has become fixed and is hereditary.

Hering found that enclosing the larger cotyledon of streptocarpus in a plaster cast so as to check the growth, the smaller and usually fugacious one grew to the size of the large one, provided the experiment was started before the small one was too old. Amputation of the large cotyledon gave the same results.

Other experimenters have directed their attention to the effect of light and gravity on the arrangement of the leaves on the stem, as well as to the effect of light on the length of the petiole and breadth of the lamina. Among these may be mentioned the work of Weisse, Rosenvinge, and others.

Goebel has shown experimentally that dampness is also one of the external influences which can change the character of xerophyllous leaves. A New Zealand species of Veronica of xerophyllous habit and scaly appressed leaves, in the seedling stage has spreading leaves with a broad lamina. Older plants can be forced into this condition in which the leaves are expanded, by growing them in a moist vessel. Gain, Askehasy, and others have shown that dampness or dryness has an important influence in determining the character of the leaves.

The results of the experiments in showing the relation of the leaf to the bud scales, Goebel regards as evidence that the foliage leaf is the original form of the two, and that the bud scale is a modification of it.

Treub conducted some interesting experiments for the purpose of determining the homology of the pappus of the Compositæ.

Gall-insects were employed to stimulate the pappus of *Hieracium umbellatum*, and it was made to grow into a normal calyx with five lobes. A recent letter from Prof. Treub states that he later repeated these experiments with other species of Compositæ with like results, but the work was not published. Kny found, in seedlings and cuttings which he experimented with, that while there was still stored food available for the roots and shoots, there was little if any dependence of one upon the other. Hering comes to somewhat different conclusions as a result of his experiments, finding that in some cases there was a slight increase of growth, while in others growth of the one was reciprocally retarded when either the other was checked in development. Numerous cases of horticultural practice in pollination of fruits shows that the form and size of the fruit, and of the adjacent parts, as well as the longer or shorter period of existence of the floral envelopes, can be influenced by pollination.

The investigations carried on by Klebs in the conjugation of Spirogyra suggest how experimentation of this kind may be utilised to determine questions which in special cases cannot be arrived at easily by direct investigation. If threads of *Spirogyra varians* which are ready for conjugation are brought into a 0·5 per cent. solution of agar-agar, in such a way that nearly parallel threads lie at a varying distance in their windings, where they are within certain limits, the conjugation tubes are developed and the zygospores are formed. But where the threads lie at too great a distance for the influences to be exerted, the cells remain sterile, and no conjugation tubes are developed. If now these threads be brought into a nutrient solution, the cells which were compelled to remain sterile grow and develop into new threads, *i.e.* they take on the vegetative, though they are fully prepared for the sexual function. Strasburger has pointed out that this may be taken as excluding the possibility of there being a reducing division of the chromosomes during the maturing of the sexual cells, a process which takes place in animals, and that the behaviour of Spirogyra in this respect agrees with what is known to take place in the higher plants, viz. that the reduction process is not one which is concerned in the maturity of the gametes. The same could be said of Polyphagus, in which Nowakowski found that before the zygospore was completely formed the protoplasm moved out and formed a new sporangium.

In *Protosiphon botryoides* Klebs was also able to compel the parthenogenetic development of the motile gametes, and the same thing was observed in the case of the gametes of Ulothrix. If we are justified in interpreting this phenomenon as Strasburger suggests, the evidence which Raciborski gives as a result of his experiments with *Basidiobolus ranarum* would support the idea that there is no reducing division in the chromosomes before the formation of the nuclei of the gametes. Raciborski found that the young zygospores of this species, in old nutrient medium where the fusion of the plasma contents had taken place, but before the nuclei had fused, if they were placed in a fresh nutrient medium the fusion of the nuclei was prevented, and vegetative growth took place, forming a hypha which possessed two nuclei—the paternal one and the maternal one. Raciborski interprets Eidam's study of the nuclear division prior to the copulation of the gametes as showing that the reducing division takes place here as in the maturation of the sexual cells of animals, and looks upon the premature germination of the zygospore as showing that a paternal and maternal nucleus possesses the full peculiarities of a normal vegetative one. However, we are not justified in claiming a reducing division for the nuclei preceding the formation of the gametes in Basidiobolus from the work of Eidam, since he was not able to obtain sufficiently clear figures of the division to determine definitely how many divisions took place, to say nothing of the lack of definite information as to the number of chromosomes. Fairchild has recently studied more carefully the nuclear division, but, on account of the large number of the chromosomes, was not able to determine whether a reduction takes place. He points out, as others have done, the similarity in the process of the formation of the conjugating cells of Basidiobolus and Mougeotia among the Mesocarpeæ, and to these there might be added the case of Sirogonium, in which the paternal cell just prior to copulation undergoes division. The division of the copulation cells in Basidiobolus, Mougeotia, Sirogonium, &c., suggest at least some sort of preparatory act; but whether this is for the purpose of a quantitative reduction of the kinoplasm, as Strasburger thinks sometimes takes place, or is a real reduction in the number of the chromosomes, must be determined by further study, so that the bearings of these experiments on the question of a reducing division must for the time be held in reserve.

One of the very interesting fields for experimental investigation is that upon the correlation processes which govern morphology of the sporophylls (stamens and pistils) of the Spermatophyta. One of the controlling influences seems to be that of nutrition, and in this respect there is some comparison to be made with the correlative processes which govern the determination of sex in plants. Among the ferns and some others of the Pteridophyta a number of experiments have been carried on by Prantl, Bauke, Heim, Buchtien and others to determine the conditions which influence the development of antheridia and archegonia. Prantl found that on the prothallia of the ferns grown in solutions lacking nitrogen there was no meristem, and consequently no archegonia, while antheridia were developed; but if the prothallia were changed to solutions containing nitrogen, meristem and archegonia were developed. All the experiments agree in respect to nutrition; with scanty nutrition antheridia only were developed, while with abundant nutriment archegonia were also developed. Heim studied the influence of light, and found that fern prothallia grow best with light of 20 to 25 per cent. Exclusion of the ultra-violet rays does not affect the development of the sexual organs. He argues from this that the ultra-violet rays are not concerned in the elaboration of the material for flower production, as Sachs as suggested. In yellow light the prothallia grew little in breadth; they also grew upward, so that few of the rhizoids could reach the substratum. Antheridia were here very numerous. After seven months these prothallia were changed to normal light, and in four months afterwards archegonia were developed.

Among the algæ Klebs has experimented especially with

Vaucheria, such species as *V. repens* and *V. ornithocephala*, where the antheridia and oogonia are developed near each other on the same thread. With weak light, especially artificial light, the oogonium begins first to degenerate. He never succeeded in suppressing the antheridia and at the same time to produce oogonia.

High temperature, low air pressure or weak light, tend to suppress the oogonia, and at the same time the antheridia may increase so that the number in a group is quite large, while the oogonium degenerates or develops vegetatively. Klebs concludes from his experiments that the causes which lie at the bottom of the origin of sex in *Vaucheria*, as in other organisms, are shrouded in the deepest mystery.

In the higher plants a number of experiments have been carried on for the purpose of learning the conditions which govern the production of staminate and pistillate flowers, or in other words the two kinds of sporophylls. From numerous empirical observations on diœcious Spermatophyta, the inference has generally been drawn that nutrition bears an important relation to the development of the staminate and pistillate flowers; that scanty nutrition produces a preponderance of staminate plants, while an abundance of nutrition produces a preponderance of pistillate plants. For a period covering three decades several investigators have dealt with this question experimentally, notably K. Müller, Haberlandt, and Hoffmann. These experiments in general give some support to the inferences from observation, yet the results indicate that other influences are also at work, for the ratios of preponderance either way are not large enough to argue for this influence alone. In a majority of cases thick sowings, which in reality correspond to scanty nutrition, tend to produce staminate plants; while thin sowings tend to produce pistillate plants. In the case of the hemp (*Cannabis sativa*), Hoffmann found that these conditions had practically no influence. He suggests that the character of each may have been fixed during the development of the seed, or even that it may be due to late or early fecundation.

In monœcious plants it has often been observed that pistillate flowers change to staminate ones and *vice versâ*, and in diœcious plants pistillate ones sometimes are observed to change to staminate ones (the hemp for example, see Nagel, 1879). K. Müller states that by scanty nutrition the pistillate flowers of Zea mays can be reduced to staminate ones.

Among the pines what are called androgynous cones have in some instances been observed. In *Pinus rigida* and *P. thunbergii*, for example, they occur (Masters). Natsuda has described in the case of *Pinus densiflora* of Japan, pistillate and androgynous flowers which developed in place of the staminate flowers, and conversely staminate and androgynous flowers in place of pistillate ones. Fujii has observed that where the pistillate or androgynous flowers of *Pinus densiflora* occur in place of the staminate ones, they are usually limited to the long shoots which are developed from the short ones of the previous year. The proximity of those transformed short shoots (Kurztrieb) to injuries of the long ones, suggested that the cutting away of the long ones might induce the short ones to develop into long ones, and the flowers which were in the position for staminate ones to become pistillate.

Fujii says, "In fact, the injuries producing such effect are frequently given by Japanese gardeners to the shoots of the year of *Pinus densiflora* in their operations of annual pollarding. But the 'Langtrieb' which is transformed from a 'Kurztrieb' of the last year does not necessarily bear female of hermaphrodite flowers in the positions of male flowers." To determine the influence of pollarding of the shoots he carried on experiments on this pine in the spring of 1895. He pollarded the shoots, so that, as he terms it, to induce the nourishment to be employed in the development of the flowers and short shoots near the seat of injury. In other cases one or two shoots were preserved while all the adjacent shoots of last year's growth at the top of the branch were removed, and, further, both of these processes were combined. Out of the forty-five branches experimented on, and on which there were no signs of previous injury, there were nine pistillate or androgynous flowers in place of staminate ones; in twenty-one branches with signs of previous injury, five were transformed, while in 2283 not experimented on, and with no signs of previous injury, only seven were transformed. Such abnormal flowers, then, are due largely to the injuries upon the adjacent shoots, and, Fujii thinks, largely to the increased amount of nourishment which is conveyed to them as a result of this.

From the experiments thus far conducted upon the determination of sex in plants or upon the determination of staminate or pistillate members of the flower, nutrition has at least some influence in building up the nourishing tissue for the two different organs or members. This can in part be explained on the ground that antheridia and staminate members of the plant are more or less short-lived in comparison with the archegonia and pistillate members, the latter requiring more bulk of tissue to serve the purpose of protection and nourisnment to the egg and embryo. It is thus evident that while some progress has been made in the study of this question, we are far from a solution of it. Experiment has proceeded largely from a single standpoint, viz. that of the influence of nutrition. Other factors should be taken into consideration, for there are evidently other external influences and internal forces which play an important *rôle*, as well as certain correlation processes perhaps connected with the osmotic activities of the cell sap.

The relation of the parts of the flower to the foliage leaves is a subject which has from time to time called forth discussion. That they are but modifications of the foliage leaf, or constituents of the leaf concept, is the contention of the metamorphosis theory, and that the so-called sporophylls are modified foliage leaves is accepted with little hesitation by nearly all botanists, though it would be very difficult, it seems to me, for any one to present any very strong argument from a phylogenetic standpoint in favour of the foliage leaf being the primary form in its evolution on the sporophyte, and that the sporophyll is a modern adaptation of the foliage leaf. Numerous cases are known of intermediate forms between sporophylls and foliage leaves both in the Spermatophyta and Pteridophyta. These are sometimes regarded as showing reversion, or indicating atavism, or in the case of some of the ferns as being contracted and partially fertile conditions of the foliage leaf. There has been a great deal of speculation regarding these interesting abnormal forms, but very little experimentation to determine the causes or conditions which govern the processes.

In 1894 I succeeded in producing a large series of these intermediate forms in the sensitive fern (*Onoclea sensibilis*). The experiments were carried on at the time for the especial purpose of determining whether in this species the partially developed sporophyll could be made to change to a foliage leaf, and yet possess characters which would identify it as a transformed sporophyll. The experiments were carried on where there were a large number of the fern plants. When the first foliage leaves were about 25 cm. high, they were cut away (about the middle of May). The second crop of foliage leaves was also cut away when they were about the same height during the month of June. During July, at the time that the uninjured ferns were developing the normal sporophylls, those which were experimented upon presented a large series of gradations between the normal sporophyll and fully expanded foliage leaves. Among these examples there are all intermediate stages from sporophylls which show very slight expansions of the distal portion of the sporophyll, and the distal portions of the pinnæ, until we reach forms which it is very difficult to distinguish from the normal foliage leaf. Accompanying these changes are all stages in the sterilisation of the sporangia (and the formation of prothalloid growths), on the more broadly expanded sporophylls there being only faint evidences of the indusia.

The following year (1895) similar experiments were carried on with the ostrich fern (*Onoclea struthiopteris*), and similar results were obtained. At the time that these experiments were conducted, I was unaware of the experiments performed by Goebel on the ostrich fern. The results he reached were the same; the sporophyll was more or less completely transformed to a foliage leaf. Goebel regards this as the result of the correlation process, and looks upon it as indicating that the sporophyll is a transformed foliage leaf, and that the experiment proves the reality here of the modification which was suggested in the theory of metamorphosis, and thus the foliage leaf is looked upon by him as the primary form. Another interpretation has been given to those results, viz. that they strengthen the view that the sporophyll, from a phylogenetic standpoint, is primary, while the foliage leaf is secondary. What one interprets as a reversion, another regards as indicating a mode of progress in the sterilisation of potentiality, sporogenous tissue, and its conversion into assimilatory tissue. It is perhaps rather to be explained by the adaptive equipoise of the correlative processes existing between the vegetative and fruiting portions of the plant which is inherited from earlier times. Rather when spore-production appears on the sporophyte could this process be looked upon as a reversion to the primary office of the sporophyte, so that in spore-production of the higher plants we may have a constantly recurring reversion to a process which in the remote past was the sole function of this phase of the plant. In this way might be explained those cases where sporangia occur on the normal foliage leaf of Botrychium, and some peculiar cases which I have observed in *Osmunda cinnamomea*. In some of the examples of this species it would appear that growth of the leaf was marked by three different periods even after the fundament was outlined; the first, a vegetative; second, a spore-producing; and third, a vegetative again; for the basal portions of the leaf are expanded, the middle portions spore-bearing, the passage into the middle portions being gradual, so that many sporangia are on the margins of quite well-developed pinnæ. These gradations of the basal part of the leaf, and their relation to the expanded vegetative basal portion, showing that the transition here has been from partially formed foliage leaf to sporophyll after the fundament was established, and later the increments of the vegetative part from the middle towards the terminal portion, shown by the more and more expanded condition of the lamina and decreasing sporangia, indicate that vegetative forces are again in the ascendency. This suggests how unstable is the poise between the vegetative leaf and sporophyll in structure and function in the case of this species.

For two successive years I have endeavoured by experiment to produce this transformation in *Osmunda cinnamomea*, but thus far without sufficiently marked results. The stem of the plant is stout, and this, together with the bases of the leaves closely overlapping, contain considerable amounts of stored nutriment which make it difficult to produce the results by simply cutting off the foliage leaves. The fact that these transformations are known to occur where fire has overspread the ground, and, as I have observed, where the logging in the woods seriously injured the stools of the plant, it would seem that deeper-seated injuries than the mere removal of foliage leaves would be required to produce the transformation in this species. It may be that such injury as results from fire or the severe crushing of the stools of the plant would be sufficient to disturb the equilibrium which existed at the time, that the action of the correlative forces is changed thereby, and there would be a tendency for the partially developed foliage leaves to form sporangia, then when growth has proceeded for a time this balance is again changed.

The theory that the foliage leaves of the sporophyte have been derived by a process of sterilisation, and that the transformation of sporophylls to foliage leaves, in an individual, indicates the mode of progress in this sterilisation, does not necessarily involve the idea that the sporophyll of any of the ferns, as they now exist, was the primary form of the leaf in that species; and that by sterilisation of some of the sporophylls, the present dimorphic form of the leaves was brought about. The process of the evolution of the leaf has probably been a gradual one, and extends back to some ancestral form now totally unknown. One might differ from Prof. Bower; the examples selected by him to illustrate the course of progress from a simple and slightly differentiated sporophyte to that exhibited in the various groups of the Pteridophyta. But it seems to me that he is right in so far as his contention for the evolution of vegetative and assimilatory members of the sporophyte, can be illustrated by a comparison of the different degrees of complexity represented by it in different groups, and that this illustrates the mode of progress, as he terms it, in the sterilisation of potential sporogenous tissue.

On this point it appears that Prof. Bower has been unjustly criticised. The forms selected to illustrate his theory were chosen not to represent ancestral forms, or direct phylogenetic lines, but solely for the purpose of illustrating the gradual transference of spore-bearing tissue from a central to a *peripheral position, and the gradual eruption and separation of* spore-bearing areas, with the final sterilisation of some of these outgrowths.

To maintain that in phylogeny the sporophyll is a transformed foliage leaf, would necessitate the predication of ancestral plants with only foliage leaves, and that in the case of these plants the vegetative condition of the sporophyte was the primary one, spore production being a later developed function. Of the forms below the Pteridophyta, so far as our present evidence goes, the sporophyte originated through what Bower calls the gradual elaboration of the zygote. All through the Bryophyta wherever a sporophyte is developed, spore production constantly recurs in each cycle of the development, and yet there is no indication of any foliar organs on the sporophyte. The simplest forms of the sporophyte contain no assimilatory tissue, but in the more complex forms assimilatory tissue is developed to some extent, showing that the correlative forces which formerly were so balanced as to confine the vegetative growth to the gametophyte and fruiting to the sporophyte, are later changing so that vegetative growth and assimilation are being transferred to the sporophyte, while the latter still retains the function of spore production, though postponed in the ontogeny of the plant.

If we cannot accept some such theory for the origin of sporophylls and foliage leaves, by gradual changes in potential sporogenous tissue, somewhat on the lines indicated by Bower, it seems to me it would be necessary, as already suggested, to predicate an ancestral form for the Pteridophyta in which spore production was absent. That is, spore production in the sporophyte of ancestral forms of the Pteridophyta may never have existed in the early period of its evolution, and spore production may have been a later development. But this, judging from the evidence which we have, is improbable, since the gametophyte alone would then be concerned in transmitting hereditary characters, unless the sporophyte through a long period developed the gametophyte stage through apospory. Bower says, in taking issue with Goebel's statement that the experiments on *Onoclea* prove the sporophyll to be a transformed foliage leaf: "I assert, on the other hand, that this is not proved, and that a good case could be made out for priority of the sporophyte; in which event the conclusion would need to be inverted, the foliage leaf would be looked upon as a sterilised sporophyll. This would be perfectly consistent with the correlation demonstrated by Prof. Goebel's experiments, as also with the intercalation of a vegetative phase between the zygote and the production of spores." In another place he says: "To me, whether we take such simple cases as the Lycopods or the more complex case of the Filicineæ, the sporangium is not a gift showered by a bountiful Providence upon pre-existent foliage leaves: the sporangium, like other parts, must be looked upon from the point of view of descent: its production in the individual or in the race may be deferred, owing to the intercalation of a vegetative phase, as above explained; while, in certain cases at least, we probably see in the foliage leaf the result of the sterilisation of sporophylls. If this be so, much may be then said in favour of the view that the appearance of sporangia upon the later formed leaves of the individual is a reversion to a more ancient type rather than a metamorphosis of a progressive order."

As I have endeavoured to point out in another place, if a disturbance of these correlative processes results in the transference of sporophyllary organs to vegetative ones on the sporophyte, "why should there not be a similar influence brought to bear on the sporophyte, when the same function resides solely in the gametophyte, and a disturbing element of this kind is introduced? To me there are convincing grounds for believing that this influence was a very potent—though not the only—one in the early evolution of sporophytic assimilatory organs. By this I do not mean that in the Bryophyta, for example, injury to the gametophyte would now produce distinct vegetative organs on the sporophyte, which would tend to make it independent of the gametophyte. But that in the bryophyte-like ancestors of the pteridophytes an influence of this kind did actually take place, appears to me reasonable.

"In the gradual passage from an aquatic life, for which the gametophyte was better suited, to a *terrestrial* existence for which it was unadapted, a disturbance of the correlative processes was introduced. This would not only assist in the sterilisation of some of the sporogenous tissue, which was taking place, but there would also be a tendency to force this function *on some of the sterilised portions of the* sporophyte, and *to* expand them into organs better adapted to this office. As eruptions in the mass of sporogenous tissue took place, and sporophylls were evolved, this would be accompanied by the transference of the assimilatory function of the gametophyte to some of these sporophylls."

Because sporophytic vegetation is more suited to dry land conditions than the gametophytic vegetation, it has come to be the dominating feature of land areas. Because the sporophyte in the Pteridophyta and Spermatophyta leads an independent existence from the gametophyte, it must possess assimilatory tissue of its own, and this is necessarily developed first in the ontogeny; but it does not necessarily follow, therefore, that the foliage leaf was the primary organ in the phylogeny of the sporophyte. The provision for the development of a large number of spores in the thallophytes, so that many may perish and still some remain to perpetuate the race, is laid hold on by the bryophytes, where the mass of spore-bearing cells increases and becomes more stable, for purposes of the greatest importance. Instead of perishing, some of the sporogenous tissue forms protecting envelopes, then supporting and conducting tissue, and finally in the pteridophytes and spermatophytes nutritive and assimilatory structures are developed. Nature is prodigal in the production of initial elementary structures and organs. But while making abundant provision for the life of the organism through the favoured few, she has learned to turn an increasing number of the unfavoured ones to good account. Acted upon by external agents and by internal forces, and a changing environment, advance is made, step by step, to higher, more stable, and prolonged periods.

While we have not yet solved any one of these problems, the results of experimental morphology are sufficient to indicate the great importance of the subject and the need of fuller data from a much larger number of plants. If thus far the results of experiments have not been in all cases sufficient to overthrow the previous notions entertained touching the subjects involved, they at least show that there are good grounds for new thoughts and new interpretations, or for the amendment of the existing theories. While there is not time for detailing even briefly another line of experiment, viz. that upon leaf arrangement, I might simply call attention to the importance of the experiments conducted by Schumann and Weisse from the standpoint of Schwendener's mechanical theory of leaf arrangement. Weisse shows that the validity of the so-called theory of the spiral arrangement of the leaves on the axis may be questioned, and that there are good grounds for the opening of the discussion again. It seems to me, therefore, that the final judgment upon either side of all these questions cannot now be given. It is for the purpose of bringing fresh to the minds of the working botanists the importance of the experimental method in dealing with these problems of nature, that this discussion is presented as a short contribution to the subject of experimental morphology of plants.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—Sir Archibald Geikie has been appointed the Romanes Lecturer for 1898.

The Delegates of the Common University Fund have appointed Mr. William John Smith Jerome Lecturer in Medical Pharmacology and Materia Medica for the years 1898–99.

Cambridge.—Mr. J. H. Grace, bracketed second wrangler 1895, has been elected to a fellowship at Peterhouse.

Mr. S. F. Harmer, Superintendent of the Museum of Zoology, has been approved for the degree of Doctor of Science.

Mr. H. K. Anderson, Demonstrator of Physiology, has been elected to a Drosier Fellowship at Gonville and Caius College.

Dr. A. A. Kanthack, of St. John's College, has been elected to the Professorship of Pathology, in the place of the late Prof. C. S. Roy.

The University Lectureship in Midwifery is vacant by the resignation of Mr. E. H. Douty. Applications for appointment are to be sent to the Vice-Chancellor by November 15.

The General Board of Studies have issued a report in which they propose that the time-honoured examination in Paley's "Evidences" shall be discontinued, and that candidates for honours shall in the previous Examination be required to pass in English, French, or German, and also in Mechanics, Physics, or Logic. The report is likely to be keenly discussed.

The State Medicine Syndicate report that in the present year seventy candidates have offered themselves for examination in Sanitary Science, and that thirty-four were approved and received the University diploma in Public Health.

The degree of M.A. *honoris causa* is to be conferred on Mr. C. R. Marshall, Assistant in Pharmacology to the Downing Professor of Medicine.

Among the new Fellows elected at St. John's College on November 9, are Mr. W. McDougall, First Class Natural Sciences Tripos, 1892-94, and Mr. T. J. I'A. Bromwich, Senior Wrangler 1895, First Class Division I. Mathematical Tripos Part II., 1896.

It is announced that Mr. Jonathan Hutchinson, F.R.S., has signified his desire to found an educational museum at Selby, his native town.

In connection with North Dakota Agricultural College and Station a new chemical laboratory is in course of construction. Its estimated cost will be about 5000*l*.

Dr. Mollier, of Göttingen, has been appointed professor of mechanical engineering in the Technological Institute at Dresden.

Science states that the U.S. Geological Survey has practically completed the distribution of the Educational Series of Rocks, 175 sets of 156 specimens each having been sent out during the past summer to universities, colleges and technical institutions in the United States. There remains a small number of incomplete sets, which will be placed in certain smaller colleges. The Educational Series were prepared by the Survey with much care, for the purpose of aiding students in acquiring a general and special knowledge of rocks, and promoting the study of geology.

The Clerk to the Drapers' Company has informed the Registrar of the University College of North Wales, Bangor, that the Company will modify, in the sense suggested by the College, the conditions attached to their grant of 1000*l*. towards stocking and equipping the College farm. The grant is therefore now made conditionally upon a further sum of 3000*l*. being raised towards the same purpose before the end of the present session. It has been arranged that students pursuing the ordinary agricultural course at the College shall in future reside for a part of that course in the immediate neighbourhood of the farm, and thus get the benefit of practical training, side by side with the theoretical instruction. The College enters upon its tenancy of Lledwigan this week.

SCIENTIFIC SERIALS.

The current number (July) of the *Monthly Weather Review* (Washington) contains a paper on the observation of halo phenomena. This is a translation of a reprint of an article by the Rev. K. Schips in the Year-book of the Natural History Association, a copy of which we have received. A committee has been formed in Germany for the study of halos, and a request is made for the regular observation of these phenomena, as it appears that the subject of meteorological optics receives no great attention, except in Japan. The paper will be found instructive to both observers and students.—The equations of hydrodynamics in a form suitable for application to problems connected with the movements of the earth's atmosphere, by J. Cottier. This contribution is of much importance to those who are studying the fundamental problem of meteorology. Mr. Cottier, who was a student of brilliant promise, unfortunately died on August 17.—Rain gushes in thunderstorms, by the editor (Prof. Cleveland Abbe). Several plausible explanations of this phenomenon have been put forward from time to time, but have been rejected as erroneous. It is at present an open question whether the gushes of rain bring about the formation of lightning, or *vice versâ*. Several suggestions are made by the editor, which require to be tested by further experiment.—Among various other notes there is an interesting one, entitled "Kites at the Chicago Conference, August 1893." This method of obtaining information relating to the upper air is daily becoming more popular, and seems likely to lead to useful results.

Bollettino della Società Sismologica Italiana, vol. iii. N. 2, 1897.—On an old mercurial seismometer designed by A. Cavalli, by G. Agamennone.—Geological observations on the Florentine earthquake of May 18, 1895, by C. De Stefani. An abstract of a memoir published in the *Annali* of the Central Meteorological Office.—Notes of earthquakes recorded in Italy (February 4–18, 1897), by G. Agamennone, the most important being the earthquake of Sicily and Calabria of February 11–12, and five earthquakes of unknown but distant origin, one on February 7, two on February 13, and two on February 15.

SOCIETIES AND ACADEMIES.

CAMBRIDGE.

Philosophical Society, October 25.—Mr. F. Darwin, President, in the chair.—The following elections were made: President—Mr. F. Darwin. Vice-Presidents—Prof. Newton, Prof. J. J. Thomson, Mr. Larmor. Treasurer—Mr. Glazebrook. Secretaries—Mr. Newall, Mr. Bateson, Mr. Baker. New Members of Council—Mr. Harker, Mr. Hutchinson, Prof. Liveing, Mr. Skinner.—The following communications were made: Electrical oscillations in wires, by Mr. H. C. Pocklington. In this paper are discussed some problems relating to electrical oscillations about wires made of perfectly conducting material and of circular cross-section. The first step is to find an expression for the electrical forces which satisfies the space differential equations, and gives infinite values for the forces near the wires. It is then shown that the arbitrary function contained in that expression can be so chosen as to make the value of the component of the electric force tangetial to the surface of the wire vanish if small quantities of the first order be neglected. The value of this arbitrary function is found in the case of a circular wire, and equations are found for the period of oscillation and the decrement of the oscillation. These equations are solved in the case when the wire is so thin that it is permissible to neglect not only its radius in comparison with the circle, but even the square of the reciprocal of the logarithm of its radius in comparison with unity. In this case the alteration in period and the damping depend on the logarithm of the ratio of the radii of the wire and the circle. As a corollary, the problem of the resonance of a complete circular resonator is discussed. It is found that when accurately tuned, the magnitude of the current induced is independent of the thickness of the wire, and that the thinner the wire the more sensitive it is to accuracy of tuning. The case of waves propagated along a helical wire is next considered, a general equation being found in which small quantities are neglected. The case when the reciprocal of the radius of the wire can be neglected is discussed in detail. For this case it is found that when the period is not great, there are two velocities of propagation possible, one with a velocity (v) measured along the wire, equal to that of light, the other with a greater velocity. If, however, the period is greater than a certain finite value, the former mode of propagation only is possible. If, however, the period is very great, the velocity of propagation may be greater than v, and if the period is so great that the product of the wave-length in free space into the diameter of the wire is very great compared with the square of the diameter of the helix, the velocity attains a limiting value equal to v when measured along the axis of the helix.—On circles, spheres, and linear complexes, by Mr. J. H. Grace. Clifford in his paper on Miquel's theorem gave an infinite series of theorems commencing with the fact that, given four lines, the circumcircles of the triangles formed by them meet in a point. The present paper contains a more general series of theorems in two dimensions, and a somewhat analogous series in three dimensions. Also the first theorem of the set for four dimensions is proved. Then the method of Klein ("Linien-Geometrie und metrische Geometrie," *Math. Ann*, v.) is used to transform these results into theorems regarding linear complexes and straight lines; and the transformation of Lie (*Math. Ann.*, v.) is used to obtain, from properties of straight lines and linear complexes, results concerning spheres and their angles of intersection.—Theorems relating to the product of two hypergeometric series, by Mr. W. McF. Orr. This paper deals with such theorems as that stated by Cayley, *Phil. Mag.*, November 1858 (Collected Papers, vol. iii. p. 268).—Reduction of a certain multiple integral, by Mr. Arthur Black. The integral dealt with is one in n variables; the subject of integration is one involving an exponential of which the index is a general quadratic function of $n+1$ variables.—On the gamma function, by Mr. H. F. Baker. This note deals with the uniform convergence of a certain limiting process.—On the lines of striction of a hyperboloid, by Mr. H. F. Baker. This note remarks on the known fact that the line of striction belonging to either system of generators is a unicursal quartic curve, and considers the parametric expression of more general forms of octavic curves with six double points.—On the action of the radiation from uranium salts on the formation of clouds, by Mr. C. T. R. Wilson. It has been shown in previous papers (*Proc. Roy. Soc.*, vol. lix. p. 338, 1896; *Phil. Trans.*, vol. clxxxix. A, p. 265, 1897) that under the action of Röntgen rays, nuclei are produced in moist dust-free air, capable of acting as centres of condensation, when the air, initially saturated, suffers a sudden expansion such that v_2/v_1, the ratio of the final to the initial volume, exceeds 1·25. Nuclei requiring exactly the same degree of supersaturation are present in very small numbers in moist dust-free air under ordinary conditions. Recent experiments show that the radiation from uranium salts introduces nuclei, again requiring exactly the same degree of supersaturation, in order that condensation may take place upon them. The nuclei are many times more numerous than in the absence of the rays.

PARIS.

Academy of Sciences, November 2.—M. A. Chatin in the chair.—Actinometry in balloons, by M. J. Violle. Actinometric observations from balloons should possess many advantages over those taken on the earth, as the complete absence of dust is assured, and the air layer is also reduced. A trial ascent in the *Balaschoff*, by MM. Hermite and Besançon, showed that the radiation from the balloon itself was a negligable quantity; but from the results obtained, it would appear that there was still above the balloon such a quantity of water as in the liquid state would form a column of several centimetres in thickness.—On the preparation and properties of the borides of calcium, strontium, and barium, by MM. H. Moissan and P. Williams. The boride of calcium is formed by heating a mixture of dry calcium borate, aluminium, and sugar charcoal in a carbon crucible in the electric furnace for seven minutes (900 ampères and 45 volts). The duration and regularity of heating has a great influence upon the yield. The boride is obtained as a black crystalline powder, so hard that it readily scratches rock crystal. Chemically it is not easily decomposed, dry hydrogen at a red heat, nitrogen at 1000°, and water at ordinary temperatures being without action upon it. Fluorine attacks it in the cold with incandescence, but the other halogens only destroy the boride at a red heat. The borides of strontium and barium are prepared in the same way, and possess analogous properties. The formula of these compounds, RB_6, is identical with that of the hydrozoates of Curtius, RN_6.—Occultation of the group of the Pleiades by the moon on October 13, 1897, at Lyons, by M. Ch. André.—Observations on the Perrine comet (November 2, 1896) made at the observatory of Rio de Janeiro, by M. Cruls.—New demonstration of the fundamental theorem of projective geometry, by M. H. G. Zeuthen.—On the determination of the integrals of a partial differential equation by certain initial conditions, by M. E. Goursat.—On the problem of M. Bonnet, by M. C. Guichard.—Compressibility of gases at different temperatures at pressures near that of the atmosphere, by M. A. Leduc.—On the atomic weights of argon and helium, by M. H. Wilde.—On the stannic acids, by M. R. Engel. A *résumé* of the work on the stannic acids, with an explanation of some of the apparent contradictions.—Use of fluorescine for the detection of traces of bromine in a saline mixture, by M. H. Baubigny. The bromine is set free by a mixture of potassium permanganate and copper sulphate, and the vapours evolved allowed to impinge upon fluorescine paper. The presence of as little as ·001 gr. of bromine in 10 gr. of common salt is shown by a reddish coloration of the paper due to the formation of eosin.—On the crystallographic identity of the dextrorotatory and lævorotatory asparagines, by M. P. Freundler. The accuracy of Pasteur's law having been called in question by M. Walden from certain experimental determinations of M. Grattarola on the two asparagines, these angular measurements have been redetermined, with the result that the deviations found are well within the limits of experimental error.—Study of the transformation of sugars occurring in olive oil, by M. C. Gerber.—Mixed grafting, by M. L. Daniel. A description of a new mode of grafting which gives better results when the two plants present marked physiological differences.—On the evolution of the black rot, by M. A. Prunet. Injection may take place through the leaves of the vine at a certain stage of development, after which the leaves lose their susceptibility to black rot. It is just before this critical period that remedial measures should be applied to the leaves.—On the age of the grits containing *Sabalites andegavensis* in the west of France, by M. Jules Welsch.—New researches on the Ostioles, by M. J. J. Andeer.

DIARY OF SOCIETIES.

THURSDAY, November 11.

Institution of Electrical Engineers, at 8.—Accumulator Traction on Rails and Ordinary Roads: L. Epstein.

Mathematical Society, at 8.—On the Poncelet Polygons of a Limaçon: Prof. F. Morley.—On an Extension of the Exponential Theorem: J. E. Campbell.—The Integral $\int P_n^s dx$ and Allied Forms in Legendre's Functions, between Arbitrary Limits: R. Hargreaves.—The Character of the General Integral of Partial Differential Equations: Prof. Forsyth, F.R.S.—The Calculus of Equivalent Statements (No. 7): H. MacColl.

FRIDAY, November 12.

Royal Astronomical Society, at 8.—On the Nature of the Orbit of γ Lupi: T. J. J. See.—List No. 4 of Nebulæ discovered at the Lowe Observatory: Lewis Swift.—*Equatorial comparisons of Uranus with 41 Libræ, and a probable Occultation of the Star by the Planet*: John Tebbutt.—On the Effect of Chromatic Dispersion of the Atmosphere on the Parallaxes of α Centauri and β Orionis; and on a Method of Determining its Effect on the Value of the Solar Parallax derived from Heliometer Observations of the Minor Planets: David Gill.—The Great Equatorial Current of Jupiter: A. Stanley Williams.—Approximate *Ephemeris of the Leonids from 1897 December 24 to 1898 April 8*: G. Johnstone Stoney.—On the Effect upon the Moon's Motion of a Hypothetical Change in the Law of Gravitation: Robert Bryant.—A Spectroscopic Method for Determining the Second and Third Contacts during a Total Eclipse of the Sun: Wm. Shackleton.—Note on a Result used by Prof. Wadsworth in several recently published Papers: H. F. Newall.

Malacological Society (in the apartments of the Linnean Society), at 8.—Malacological *Notes* made during a Journey through Russia; with *some Account* of Dredgings in the Black Sea: G. F. Harris.—Description of a New Species of *Mülleria* from India: Edgar A. Smith.—Note on a Variety of *Rhaphaulus Lorraini*, with a List of the known Species: Edgar A. Smith.—On *Streptaxis gracilis*, a New Species from Ceylon: Oliver Collett.—Revision of the New Zealand Rissoidæ: H. Suter.

Physical Society (in the rooms of the Chemical Society), at 4.—Council *Meeting.*——*At 5.—On the Isothermals of Ether: J. Rose-Innes.*—On the Variation with Temperature of the Electromotive Force of the H-Form of Clark Cells: F. S. Spiers and F. Twyman.

TUESDAY, November 16.

Zoological Society, at 8.30.—On British Medusæ: E. T. Browne.—On Three Consignments of Butterflies collected in Natal in 1896 and 1897 by Guy A. K. Marshall: Dr. A. G. Butler.—On the Sydney Bush-Rat (*Mus arboricola*): Edgar R. Waite.

Mineralogical Society, at 8.—Anniversary Meeting.—Election of Officers and Council.—On Augelite from Bolivia: L. J. Spencer.

Institution of Civil Engineers, at 8.—The Manchester Ship Canal; Sir E. Leader Williams.—The Eastham Division: Whately Eliot. The Runcorn Division: Sir E. Leader Williams. The Irlam Division: W. O. E. Meade-King.

Royal Statistical Society, at 5.30—Notes on the Subjects discussed at the Meeting of the International Statistical Institute at St. Petersburg, *1897*: *Major* P. G. Craigie.

Royal Photographic Society, 12 Hanover Square, W., at 8.—A Review of Triple Printing Methods: E. Sanger Shepherd.

WEDNESDAY, November 17.

Society of Arts, at 8.—The Colonies: their Arts, Manufactures, and Commerce: Sir Owen Tudor Burne.

Geological Society, at 8.—The Geology of Rotuma: J. S. Gardiner.—A Geological Survey of the Witwatersrand and other Districts in the Southern Transvaal: Dr. F. H. Hatch.—Observations on the Genus *Aclisina* de Koninck, with Descriptions of British Species and some other Carboniferous Gasteropoda: Jane Donald.

Entomological Society, at 8.—Some Results obtained from the Hybridisation of Allied Species: J. W. Tutt.

Royal Meteorological Society (at the Institution of Civil Engineers), at 7.30.—Results of a Comparison between the Sunshine Records obtained simultaneously from a Campbell Stokes Burning Recorder and from a Jordan Photographic Recorder: Richard H. Curtis.

Royal Microscopical Society, at 8.

Sanitary Institute, at 8.—A Discussion on the Pollution of Water Supplies by Encampments of Hop-Pickers, Casual Workers, Tramps, &c.: to be opened by Prof. W. H. Corfield, in reference to the Dangers of Pollution of Municipal Water Supplies; and by Miss M. A. Chreiman, in reference to the Sanitary Control of Hop-Pickers, &c.

THURSDAY, November 18.

Royal Society, at 4.30.—Account of a Comparison of Magnetic Instruments at Kew Observatory: C. Chree, F.R.S.—Note on the Influence of very Low Temperatures on the Germinative Power of Seeds: H. T. Brown, F.R.S., and F. Escombe.—On the Structure and Affinities of Fossil Plants from the Palæozoic Rocks. II. On *Spencerites*, a New *Genus of Lycopodiaceous Cones from the Coal Measures, founded on the Lepidodendron Spenceri* of Williamson: D. H. Scott, F.R.S.—The Histology of the Cell-wall, with special reference to the Mode of Connection of Cells: W. Gardiner, F.R.S.—Mathematical Contributions to the Theory of Evolution. IV. On the Probable Errors of Frequency Constants, and on the Influence of Random Selection on Variation and Correlation: Prof. K. Pearson, F.R.S., and L. N. G. Filon.—On the Geometrical Treatment of the "Normal Curve" of Statistics, with especial reference to Correlation, and to the Theory of Error: W. F. Sheppard.

Linnean Society, at 8.—On *Pontobdellos mannarensis*: Prof. A. Dendy.—On Haddonia, a New Genus of Foraminifera: F. Chapman.

Chemical Society, at 8.—On the Decomposition of Camphoric Acid by Fusion with Potash or Soda: Dr. A. W. Crossley and W. H. Perkin, jun., F.R.S.—Experiments on the Synthesis of Camphoric Acid: W. H. Bentley and W. H. Perkin, jun., F.R.S.—The Action of Magnesium on Cupric Sulphate Solution: Dr. Frank Clowes and R. M. Caven.—Properties and Relationships of Di-hydroxytartaric Acid: H. J. Horstman Fenton.

BOOKS, PAMPHLETS, and SERIALS RECEIVED

Books.—Memorials Journal and Botanical Correspondence of C. C. Babington, F.R.S. (Cambridge, Macmillan and Bowes).—*North America.* Vol. 1. Canada and Newfoundland: S. E. Dawson (Stanford).—Resultate der Wissenschaftlichen Reforschung des Balatonsees, Zweiter Band, Erster Theil (Wien, Hölzel).—Bau und Leben unserer Waldbäume: Dr. M. Büsgen (Jena, Fischer).—The Practice of Massage: A. S. Eccles, 2nd edition (Baillière.—Air, Food, and Exercises: Dr. A. Rabagliati (Baillière).—Gases: their Constitution and Functions: S. J. THE MATHEMATICS USED IN CONNECTION WITH PHYSICS.

The Theory of Electricity and Magnetism; being Lectures on Mathematical Physics. By A. G. Webster, Assistant Professor of Physics, Clark University, Webster, Massachusetts. Pp. xii + 571. (London: Macmillan and Co., Ltd., 1897.)

THE aim of the writer, according to the preface, in the preparation of this volume has been to present to the students the results of the Maxwellian theory as it stands at present, after the labours of Faraday, Maxwell, Helmholtz, Hertz, and Heaviside.

Prof. Webster is a somewhat young man of marked promise, whose contributions to the discussions in Section A of the British Association formed one of the features of the meeting of that section at Toronto this year, and the book shows that he is fully capable of appreciating the mathematical significance of physical facts. It is doubtful, however, whether a student would be able to appreciate the physical significance of the mathematical theory from reading it. Possibly the students of the Clark University, when listening to such lectures as are given in this treatise, have the physical meanings of the various mathematical processes explained to them. If not, they must possess an exceptional amount of ability to enable them to arrive at correct physical interpretations of the mathematical equations.

The first fifty-two pages of the book are occupied with a short summary of the principles of the vector calculus, the definitions of variables, functions, differential coefficients, definite integrals, line and surface integrals, something about the calculus of variations, &c. It is not quite obvious what is the object of giving this, since a student who was capable of following the book would understand the meaning of a differential coefficient before opening it; or if, on the other hand, he was ignorant of the differential and integral calculus, he would require far more detailed information than is given in these fifty-two pages before he could tackle triple integrals, vector differential operators, &c., which are used quite early in the book.

Is it correct to say that, "following the usage of the majority of writers, we shall denote

$$\frac{\delta^2}{\delta x^2} + \frac{\delta^2}{\delta y^2} + \frac{\delta^2}{\delta z^2}$$

by Δ," seeing that many writers, including Thomson and Tait, use ∇^2, and Maxwell $-\nabla^2$?

Gauss' theorem may undoubtedly be stated as a piece of mathematical analysis, as it is done on pp. 75–78; but the theorem would be perfectly useless if gravitational, electric, and magnetic forces did not vary as the inverse square of the distance. When, therefore, the theorem is divorced from all physical application or interpretation, is not the student less likely to grasp it and to remember it?

The last section of the introductory chapter, which brings us to p. 91, discusses the theory of functions of a complex variable with clearness and conciseness; and this section might with advantage have been extended, and some of the earlier portion of the book omitted.

Part i., which commences on p. 91, is on the "Theory of Newtonian Forces"; but forces as realities, and not merely letters which satisfy a number of equations, have not much existence in the chapter. Take, for example, d'Alembert's principle described on p. 107 This principle is in reality the result of an argument based on Newton's laws, and leads to a valuable set of equations in dynamics. The reader, however, is not told this, but only that the analytical statement of d'Alembert's principle is given in Lagrange's equation of virtual velocities. This equation, Mr. Webster rightly states, involves all the internal forces, and so the student might not suspect that the essence of d'Alembert's principle was the elimination of these internal forces.

The rest of the Part i. is good, the subject of attractions being well and lucidly treated. Does not, however, the introduction of the *n* axes of the harmonic of the *n*th degree add unnecessary difficulty, and somewhat hide the beauty of harmonic analyses? For students who already possess a good knowledge of magnetism, the treatment of polarised distributions will be useful.

Although the title of this book, as given on the cover, is "Electricity and Magnetism," it is not until p. 243, or nearly the middle of the book, that we come to the portion that deals specially with electricity. The statement of the general problem of electrostatics, as given at the beginning of § 135, is insufficient since, as pointed out, any number of solutions could be given to it. The method, however, which is indicated for the solution of the problem is correct, and leads in a neat way to the conception of coefficients of induction from which the coefficients of potential are deduced.

§ 151, on Green's function, like much of the matter in the book, is divorced from its physical application, so that a student will hardly see the physical nature of the problem that Green set himself to solve, or the method by which he solved it. In fact, the author criticises Green's work as follows:—

> "Reasoning depending on such physical facts was frequently made use of by Green, and while not legitimate for purposes of mathematical demonstration, is frequently of service to the physicist."

The discussion, however, of the application of conjugate functions is good.

It is not the custom in this country to call the conductor of a Wheatstone's bridge, in which the galvanometer is inserted, "the bridge wire," and we are not aware that this practice is followed in America either.

On page 357 the author defines μ as the ***inductivity*** of the medium, and explains that this becomes specific inductive capacity in the electric case, and permeability in the magnetic. This analogy is, of course, quite correct, but it is carried too far when the same letter μ is used for specific inductive capacity on some pages and for magnetic permeability on others. In considering the dimensions of the electrostatic and electromagnetic systems of units, the propagation of waves, &c., the beginner might expect to find μ instead of which he finds $\epsilon\mu$; the meaning, however, of this ϵ does not seem to be given, and he is left to discover for himself that this ϵ stands for the specific inductive capacity for which μ has been previously employed.

We should prefer to say that the *absolute* dimensions of specific inductive capacity and of permeability were yet unknown rather than they were "arbitrary," and we do not agree with the statement that attempts to settle their absolute dimensions are evidently based upon misconceptions of the theory of dimensions.

The statement that "for magnetic bodies as the force increases μ diminishes" is generally correct, but not sufficiently guarded, seeing that the very opposite is the case for small forces; and more explanation is required as to the meaning, or the necessity, of the statement:—"The variability of μ does not affect the validity of Ohm's Law, which determines the distribution of the laws of induction."

The last chapter in Part ii., on the conduction in dielectrics, contains some interesting work, such as that on the effect of heterogeneity.

Part iii. deals with the electromagnetic field in a lucid and satisfactory manner. We feel somewhat divided in our judgment regarding Mr. Webster's inability to respond to Boltzmann's appeal that Maxwell's notation should be followed. It will undoubtedly be somewhat perplexing for the student to have to employ X, Y, Z for the components of electric field intensity when he reads this book, and for the components of a mechanical force when he is studying Maxwell's classical treatise. But Mr. Webster is an American, and the secret of the success of his countrymen lies in their having gone ahead instead of merely following precedent. Hence, whatever may be the wrench we feel at being torn away from our time-honoured notation, we must respect Mr. Webster's independence in employing what he considers a better one.

The book finishes with an excellent introduction to the theory of electromagnetic waves, which deals with the more important points of this subject in a clear and concise manner. The statement made on page 550, that the matter on the preceding seventeen pages applies only to a submarine cable of infinite length, should have come much earlier; for, on reading these pages, we certainly thought that the author was under the mistake of imagining that the treatment applied equally well to a finite cable.

On page 536 the author pokes fun at established authority by giving more than one reason why long-distance telephony has not existed in England, and on page 547 he sits in judgment on Mr. Heaviside in an equally humorous way, although in this case the fun is not intentional on the part of the author.

The book is on the whole distinctly good, and any one who has mastered it will possess a sound acquaintance with the most important parts of mathematical electricity. The absence of reference to experimental methods is, as stated in the preface, intentional, and, of course, no practical applications of electricity are referred to. But, even if this system has been followed as a protest against those who forget that the practice of to-day was the theory of yesterday, we would suggest that a course of "Lectures on Mathematical Physics" may fitly contain explanations of the physical interpretations of the equations developed without running the risk of appearing to pander to the needs of the electrical contractor.

W. E. A.

THE ELECTRICAL PHENOMENA OF NERVE.

Lectures on Physiology. (First Series.) *On Animal Electricity.* By A. D. Waller, F.R.S., &c. Pp. viii + 144. (London: Longmans, 1897.)

As Fullerian Professor of Physiology, Dr. Waller has published a series of lectures on the electrical properties of nerve, in which he tells us that his aim has been to give "an exposition of the principal data" relating to the subject. Such of these data as have been derived from his own experiments have been already made known by him in his published papers; but the physiological reader will find it much easier to appreciate their value, now that they are placed before him in connection with facts already known to him. A point of great scientific interest in Dr. Waller's work consists in the circumstance that he has adopted and strictly adhered to a uniform method of "testing" the physiological conditions of a nerve. The gratitude of the reader is further excited by the perspicuity with which the method itself and the first fruits of its application are described, as well as by a vividness of style which makes him feel as if he had been present at the demonstrations.

Dr. Waller's object is to prove that the phenomenon by which a separated nerve most strikingly shows its vitality—the negative variation of du Bois-Reymond—is also a measure and criterion of the physiological condition of the nerve. For this purpose he employs an automatic arrangement by which at regular intervals of a minute, the appropriate "stimulus" for producing this effect is applied to the nerve, at the same time that the electrical "response" made by the nerve is recorded photographically. The effect thus recorded—the negative variation just mentioned—is the *diminution* of the so-called nerve current, the amount of which diminution is indicated by the deflections of a galvanometer connected with the nerve in the usual way. Consequently, so long as the strength and duration of the stimulus (a succession of induction currents led through the nerve at a distance from the part under observation) remains constant, the perfect uniformity of the periodical deflection indicates that the state of the nerve is unaltered; and the effect of any other condition, as, *e.g.* acid or alkaline reaction, change of temperature, &c., manifests itself by augmenting or reducing the deflection. As evidence that the deflection itself is a "vital" one, that is, one belonging to the living nerve as such, it is shown that the transient loss of function which follows the action of the vapour of ether is accompanied by an equally transient disappearance of the normal electrical reaction of the nerve, and again, that the presence of carbon dioxide in the saturated atmosphere in which the nerve is placed for observation, even in the smallest quantity, augments in an equally remarkable way the power of the nerve to respond to stimulation.

In the third lecture Dr. Waller sets forth further interesting facts relating to the mode of action of carbonic acid gas, and compares it with the effects of repeated stimulation, drawing certain inferences as to the agency of this body in producing fatigue, which it would be out of place to criticise here.

The fifth and sixth lectures are devoted to the elucidation of certain changes in the electromotive properties of living nerve, to which half a century ago du Bois-Reymond applied the term electrotonus. Using the method of observing and recording the responses to periodical automatic stimulations already referred to, Dr. Waller demonstrates du Bois' extrapolar electrotonic currents in such a way as to enable the audience to judge of their correspondence with phenomena of the same kind observed in "core models" (*i.e.* cylindrical conductors of which the cores are metallic, the sheaths soaked with solutions of electrolytes), and finally proves, as before, with the aid of ether vapour, that although these phenomena resemble those of physical polarisation so closely, they are, notwithstanding, dependent on a vital activity which the nerve loses and recovers again when for a few minutes put to sleep by the anæsthetic. In the last lecture Dr. Waller goes into the rather more recondite phenomena of "polarisation increment and decrement." His mode of exposition of this subject is so original that one begins to fear that he is about to demolish the interpretation of these phenomena which has been given by his distinguished predecessors in this field of investigation. Happily it is not so. When the time comes for explaining, the instructed reader is gratified to find that although the terms employed are peculiar and unusual, there is nothing abnormal about the doctrine. "Active tissue is zincative, resting tissue is zincable." Consequently in a living nerve through a certain bit of which a battery current is flowing, the anode is more zincable than the kathode; for the living substance of the nerve is at rest at the anode, awake at the kathode. But what does zincable mean? It is a word which Dr. Waller proposes to introduce into scientific terminology because he cannot find an English equivalent for the German "leistungsfähig." Regarding the "Leistung" of a nerve to be chiefly electrical, its "Leistungsfähigkeit" is its "capability of being aroused to electromotive action" (p. 83)—a property which he emphatically distinguishes from "excitability," rightly holding that this word ought only to be used to denote the facility with which a response is evoked.

Dr. Waller's explanation of the increment and decrement is that the diminished excitability which is the well-known effect of the anode during the flow of a voltaic current along a nerve, is necessarily associated with what he calls increased zincability. Hence if the nerve passes from the electrotonic into the excited state, those parts which are most zincable are most susceptible of excitatory change. The point which is thus enforced—that is, the association of increased capability with diminished promptitude to reaction—is a fundamental one in the physiology of all excitable tissues. There can be no doubt that in relation to the phenomena now in question, it has been brought out in a more striking way than before by Dr. Waller's excellent forms of experiment, his lucid description, and the admirable diagrams which make those descriptions easy to follow.

J. B. S.

NOTES OF A NATURALIST AND ANTIQUARY.

Memories of the Months; being pages from the Notebook of a Field Naturalist and Antiquary, to wit, Sir Herbert Maxwell, Bart., M.P. Crown 8vo. Pp. xii + 300. (London: Edward Arnold, 1897.)

THE competitive exactions of business and social pleasure have their reaction. An increasing number of people are turning with interest to the study of natural history, and are willing to learn from those who can write about it. This is a hopeful sign to those who believe that the social health and physical standard of the nation depend in large measure on affection for country life, and that it would be an evil thing should field and flood cease to afford attractions for active minds. As Sir Herbert Maxwell truly remarks, no head is constructed to carry about an explanation of half the things noticed in the course of a single morning's walk; but if notes are made at the moment of what attracts the eye, be it a landscape, a ruin, a battle-field, a flower, bird, or insect, recourse may be had at home to the information abundantly stored in books, and the significance of what seemed commonplace or trivial becomes evident at once. Without attempting to become a specialist himself, every one has at command the accumulated fruits of the labours of specialists.

Acting upon this conviction, it would appear that Sir Herbert Maxwell has long been in the habit of making wayside notes on a variety of subjects, and from time to time has amplified and published them for the benefit of others.

His method of presenting them to the reader is not very new, as will be perceived by those who are acquainted with the Rev. Robert Willmott's "Summer Time in the Country," Mr. Oswald Crawfurd's "Round the Calendar in Portugal," Prof. Miall's "Round the Year," and other books of a similar nature; and it might, perhaps, have been better to have arranged his miscellaneous and fragmentary notes under zoological, botanical, and antiquarian headings, instead of grouping them, as he has done, under the headings of the months to which more often than not they have no particular relation. This plan would have been more convenient to specialists as affording them the opportunity of at once finding all that relates to their own subject, instead of having to search for scattered notes through three hundred pages.

No one, however, who dips into this little volume will begrudge the time bestowed upon it, for whether he be in search of particular information on a given subject or not, he will perforce linger upon many a page wherein he will find both amusement and instruction.

What more amusing, for example, than the author's account (pp. 259-266), of the attempts made to decipher the inscription on the celebrated Ruthwell Cross, variously interpreted—and by experts too—as Runic

Old Norse, and Anglo-Saxon; or his explanation (p. 184) of the reason for keeping cattle in herds.

For instruction we may turn to such chapters as those on the "Revival of a primitive fauna," on "West coast meteorology," or on "Assisted vision." Some of the pleasantest reading is to be found in the pages which give the results of the author's out-of-door observation. Here, for example, is a note on the enmity between bees and butterflies:—

> "All kinds of stonecrop possess peculiar attractions for bees and butterflies owing to their abundant secretion of honey. One of the tall growing kinds, *Sedum spectabile*, is by far the handsomest. It is the latest to flower, and its great, flat, rosy corymbs are irresistible to that splendid autumn butterfly, the Red Admiral. . . . I have been watching a number of these robust insects busy on the large stonecrop—so busy as to allow me to use a lens on them. There were no less than sixteen Admirals at work on one group of *Spectabile* stonecrop. The honey bees, however, interfered with them, and it was curious to see how shrewdly a Red Admiral would sheer off at the approach of a bee of less than one-tenth of his own bulk. . . . Now, how do butterflies learn to dread a bee? How do they know that bees are armed? It can hardly be by experience, for no butterfly could survive the stab of a bee's sting. It is part of the mystery enveloping the intelligence of animals not personally educated by their parents. . . . The phases of insect life—the egg abandoned by the parent, the stages of larva, pupa, and imago—seem specially calculated to interfere with hereditary knowledge, and to prohibit the communication of instruction. . . . This avoidance of bees by butterflies seems to be an instance of pure instinct."

On another page, in the course of some remarks on the choice of food by animals, the author alludes to the fact that some creatures will thrive upon plants which to others are poisonous, and instances the case of the Spurge Hawk Moth (*Deiliphila euphorbiæ*), of which the caterpillar feeds exclusively on the Sea Spurge, although this plant secretes an acrid juice "so painfully poisonous that it is difficult to imagine a digestive apparatus competent to deal with it." He might have mentioned the still more curious case of the caterpillar of another moth, *Deiopeia pulchella*, which feeds on the virulent poison contained in the seed of the Esere or "Ordeal Bean" of Old Calabar (*Physostigma venenosum*), and is unaffected by it (*cf.* Dr. T. R. Fraser, *Ann. Mag. Nat. Hist.*, May 1864).

We should like to know the authority for the statement (p. 141) that in the lines from the "Midsummer Night's Dream" (So doth the woodbine the sweet honeysuckle gently entwist), Woodbine means the Bittersweet or Deadly Nightshade. This interpretation appears to have the sanction of Dr. Prior in his "Popular Names of British Plants," but is opposed to the view of Canon Ellacombe, who has made a special study of the "Plant-lore of Shakespeare."

We have noted other passages on which criticism might be offered did space permit; but enough has perhaps been said to indicate the scope of the volume. While too much in the nature of a scrap-book to entitle it to praise as a literary effort, it has the merit of being distinctly entertaining, and of conveying in a light, pleasant style a variety of information on subjects of more or less interest.

OUR BOOK SHELF.

Notes on Micro-organisms Pathogenic to Man. By Surgeon-Captain B. H. S. Leumann, Indian Medical Service. Pp. 96. (London: Longmans, Green, and Co., 1897.)

THIS compact and well-written little volume does not make any pretensions to be a text-book in the ordinary sense of the word, and we should be sorry if the "students and practitioners" for whom it is intended should in their turn make any pretensions to a knowledge of the subject after its perusal. Indeed, students and practitioners "who have no opportunity of working at the subject themselves, or time to read a larger book," had better remember the old adage, a little learning is a dangerous thing. Bacteriology, unfortunately, suffers at the present time from the idea that it is essentially a popular science—that it is a subject well within the comprehension and well within the grasp of any one who chooses to hold out his hand for it. Thus we too frequently find it taken up by totally unqualified persons, and the results of their recondite researches serve to bring the whole domain of microbes into disrepute. We do not quarrel with Surgeon-Captain Leumann's little book, for it is clearly and concisely written, and makes every endeavour to be accurate and up to date; and of particular interest is the local colouring, if we may use such an expression, which characterises it in dealing with the most recent work in India on plague and cholera. We have no desire to depreciate these notes, but we do regret that the author encourages the practice of reading about bacteria instead of working at them in a class of professional men who ought certainly to be able to do something more substantial than talk about them. Bacteriology to be of any value must be studied in the laboratory; and without a practical acquaintance with micro-organisms, the latest and most exhaustive manual "made in Germany" will fail to do more than acquaint the reader with the superficial phraseology of the subject.

The Winter Meteorology of Egypt and its Influence on Disease. By H. E. Leigh Canney, M.D. (Lond.), &c. Pp. 72. (London: Ballière, Tindall, and Cox, 1897.)

TO people who, for health's sake, pass the winter in Egypt, and to practitioners who wish to know the climatic conditions of the various health resorts of the country, this book will be an invaluable possession. The volume comprises a paper read before the Royal Meteorological Society last December, and one read before the recent International Congress of Medicine at Moscow. The first of these papers contains the results of a series of meteorological observations made under precisely comparable conditions during three or four winters in Egypt. The stations at which observations were made were Cairo, Mena House, Helouan, Luxor, Assouan, Valley of the Tomb of the Kings, and the crest of the Libyan Hills. As self-recording thermometers and hair-hygrometers were used at each station, valuable data were obtained on the diurnal variation of temperature and humidity. It appears from the discussion of the observations that the climate of Egypt is influenced by the Libyan or Western Desert, the Mediterranean Sea, and the extent of cultivated land.

The second part of the treatise provides the medical profession with a valuable guide to the therapeutic influences of the climates of different health stations in Egypt. Practitioners who have not been able to visit the country will find this section most serviceable.

Appended to the volume are several clear and instructive diagrams showing, for the six months from November 1895 to April 1896, the temperature and relative humidity at various hours of the day at Helouan, Mena House, Luxor, and Assouan; the drying power of the air at the temperature of the air; and the drying power of the air at the temperature of the body.

Les Fours Électriques et leurs Applications. By Ad. Minet. Pp. 178. (Paris: Gauthier-Villars et Fils; Masson et Cie.).

ALL thermo-electric effects in which electricity is the prime agent are regarded by the author as coming within the scope of the title of this book, the grounds being that all forms of apparatus for converting electrical energy into heat, come under the generic head of *fours électriques.* The book thus includes not only descriptions of electric furnaces in which temperatures approaching four thousand degrees are reached, but also of simple conductors and resistance coils raised a few degrees above the temperature of the atmosphere by the electric current. The first part of the volume is devoted to an account of the heating effects of electricity; it includes descriptions of the heat produced by a current passing through a metallic resistance, the maximum temperatures of conductors, and electric heating generally. The remaining three parts deal with the electric arc and arc carbons of various forms, electric furnaces and their applications, and carbide of calcium and acetylene.

It will thus be seen that portions of the book are not exactly pertinent to the title, nevertheless they assist the reader to a clear understanding of electro-thermal phenomena. The section on electric furnaces is a concise account of the various forms of furnace devised for different purposes.

The book belongs to the Encyclopédie scientifique des Aide-Mémoire series edited by M. Léauté.

Bibliography of X-Ray Literature and Research (1896-1897); being a Ready Reference Index to the Literature on the Subject of Röntgen or X-Rays. Edited by Charles E. S. Phillips. With an Historical Retrospect, and a chapter of "Practical Hints." Pp. xxxvii + 68. (London: *The Electrician* Printing and Publishing Co., Ltd.)

THE work before us gives, in a handy and succinct form, a good deal of information respecting the literature of X-rays. The subject proper of the volume is prefaced by a brief historical retrospect, in which, however, the average worker in physics will find little but what is already known to him, and a short chapter of practical hints intended "to appeal more especially to physical students about to turn their attention to high vacua research." The main and most valuable portion of the book is the bibliography, and this should certainly prove of utility to investigators in this branch of science. The volume, so far as we have been able to test it, appears to have been compiled with great care, and certainly a mass of useful knowledge is here gathered together in a form easy of reference.

Die Meteoriten in Sammlungen und ihre Literatur, nebst einem Versuch den Tauschwert der Meteoriten zu bestimmen. Von Dr. E. A. Wülfing. Pp. xlvi + 460. (Tübingen: Laupp, 1897.)

THE author has sought information relative to the meteorite collections, public and private, from those in charge of them, and has collated and indexed the results in the form of an alphabetical list, giving for each preserved meteorite a statement of the date of fall or find, a list of the more important memoirs relating thereto, and the weights preserved in the various collections. The work has been carefully done, and will be very useful to collectors of these extra-terrestrial bodies. As regards the pecuniary values to be assigned to the meteorites, we are afraid that the dealers will eschew all such mathematical calculations as are suggested by the author, and will in each case get, as heretofore, what they can.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Rediscovery of the Tile-fish ("Lopholatilus").

I AM indebted to Dr. John Murray for drawing my attention to an error in the address which I had the honour of delivering before the Linnean Society on May 24. In referring to the discovery and subsequent remarkable disappearance of the Tile-fish (*Lopholatilus chamæleonticeps*), I stated that since the year in which the extraordinary mortality in this species had been observed (1882), "no specimen of the fish has ever been found."

I must take an early opportunity of correcting this error, which I might have easily avoided by reading more carefully the concluding paragraphs of Goode and Beane's account of the Tile-fish in "Oceanic Ichthyology," p. 288, from which I may be allowed to quote as follows:

"In the fall of 1892, Colonel Marshall McDonald, the Commissioner of Fisheries, made another attempt to discover the fish, and was successful, obtaining it from the following stations [five stations are enumerated, on which eight specimens were caught]. The Tile-fish then is restored to the list of existing species of our North Atlantic coast, and it is probable that in time it may attain to its former abundance. The temperature-investigations made by Colonel McDonald have been carefully discussed by him, and he is convinced that the destruction of *Lopholatilus* was due entirely to climatic causes."

What these climatic causes are we learn from a report by Prof. William Libbey, jun., published in the U.S. Fish Commission Report for 1893 (Washington, 1895, 8vo), p. 32; they consist in a variation of the relations of the Gulf Stream to the Labrador current, affecting the temperature of a certain area inhabited by the fish. A lowering of the temperature by the latter current is believed to have caused the sudden mortality, whilst a subsequent invasion of warm Gulf Stream water would allow the fish to gradually reoccupy the depopulated area.

Kew Gardens, November 14. A. GÜNTHER.

The Exploration of the Air by Means of Kites.

THE highest kite ascent, described in NATURE of October 7, was in turn exceeded here by more than 1800 feet on October 15, when excellent meteorological traces (of which a facsimile is enclosed) were brought down from a height of 11,086 feet above Blue Hill. The flight was effected with only four kites, and the ascent and descent occupied but four and a half hours. Excepting a more rapid decrease of temperature with increase of elevation, the results agree with those already stated for the previous high flight.

I now desire to call attention to the fact that the deductions from our automatic records obtained with kites seem to confirm, in general, the conclusions reached by Messrs. Welsh and Glaisher from their observations in free balloons many years ago in England. For example, we find also that the most rapid decrease of temperature with height occurs usually in the lower mile of air during the daytime, and, even with no visible clouds, that damp strata often exist in the dry air of the upper regions. A discussion by Mr. Clayton of more than one hundred meteorological records, obtained with kites since 1894, is now in the press, and will form an appendix to Part i. vol. xlii. of the *Annals of the Astronomical Observatory of Harvard College.*

A curious illustration of how identical methods sometimes may serve diametrically opposed investigations, is the application of the deep-sea sounding apparatus of Sir William Thomson (now Lord Kelvin) to bring *down* these aerial soundings.

A. LAWRENCE ROTCH.

Blue Hill Meteorological Observatory, November 1.

Lord Rayleigh's Proof of Van 't Hoff's Osmotic Theorem.

IN what follows I shall understand by "Van 't Hoff's Osmotic Theorem," the statement, that if P, V be the osmotic pressure and volume of unit mass of a solute, and p, v the gas-pressure and volume of the same mass of the same substance supposed gaseous at the same temperature, then $pv = PV$.

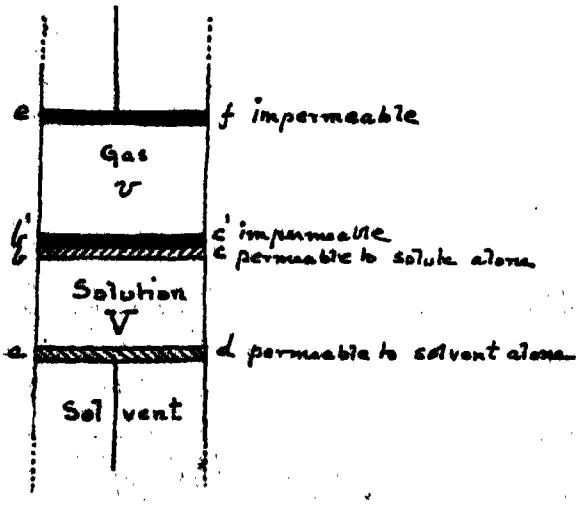
As is well known, this theorem was originally proved by Van 't Hoff by employing a differential thermodynamical process, which led to the result $vdp = VdP$. Assuming Henry's law in the form $\frac{v}{V}$ = const., and Boyle's law for both gas and solution, *i.e.* pv = const., and PV = const., the above result follows at once. Substantially the same proof was given by Nernst in his "Theoretische Chemie."

Quite recently, however, a new and novel proof of the same theorem was published by Lord Rayleigh in the columns of NATURE. In this proof Lord Rayleigh avoids the assumption of the equation PV = const., and herein lies a definite advance in the subject. The proof is based on the validity of Boyle's law for the gas, and Henry's law; but as the solvent is assumed to be involatile, it was objected by Lord Kelvin that the great majority of cases would thereby be excluded. So far as I can see, a small addition to Lord Rayleigh's proof will suffice to free it from this objection.

Besides this, I think that Lord Rayleigh's proof may be generalised so that even the assumption of Boyle's law for the gas is not required, at all events formally.

The primary assumption to be made is that for isothermal equilibrium the ratio of the concentrations of the substance in question, as gas and as solute, remains constant. This is usually known as the Distribution-Law, and cannot be regarded as a mere deduction from Boyle's law, and a certain form of statement of Henry's law. Recent research rather goes to show that it is a fundamental law of great generality. Accordingly I venture to employ Lord Rayleigh's method of proof, as follows.

ad and *ef* are two pistons, *ef* being impermeable, and *ad* permeable for the solvent alone. *bc* and *b'c'* are two fixed walls, of which *b'c'* is impermeable and *bc* permeable for the solute only. The piston *ad* is for the present fixed, and encloses a volume V of solvent between itself and *bc*. Suppose the cylinder to have unit section, and denote height of upper piston above the fixed semi-permeable wall by x. The whole process is conducted at the constant temperature t. Suppose now that between *ef* and *b'c'* there is enclosed a quantity of the solute as gas, of volume v, temperature t and pressure p, the amount being so chosen that it is just sufficient to saturate the volume V of solvent at this temperature and pressure. Let ρ denote density of the gas and suppose $p = \rho^2\phi'(\rho)$ to be the isothermal equation of state for the gas, where ϕ is an undetermined function. Take as unit of mass the mass of the enclosed gas. Allow the upper piston to rise reversibly to a height x, which is a very great multiple of the initial height. The work done in this process is:—



$$\int_v^x pdv = \phi\left(\frac{1}{v}\right) - \phi\left(\frac{1}{x}\right).$$

Let *b'c'* be removed and the gas reversibly compressed, whereby it is reversibly absorbed, the small amount of irreversibility at the beginning becoming vanishingly small in the limit. Denoting by c the concentration of the solution at any moment, we have during the downward stroke:—

$$px + cV = 1$$
$$\frac{c}{\rho} = \text{K (Distribution-Law).}$$

The work done on the system in this stroke, whereby the gas is just completely absorbed, is given by:—

$$\int_0^x pdv = \Big[\phi(\rho)\Big]_{x=x}^{x=0}$$
$$= \phi\left(\frac{1}{\text{KV}}\right) - \phi\left(\frac{1}{x+\text{KV}}\right).$$

But $\frac{1}{\text{KV}} = \frac{1}{v}$, since by hypothesis $\frac{1}{\text{V}}$ and $\frac{1}{v}$ are the concentrations of the substance in solution and as gas respectively, for equilibrium at t and p. Thus the work done so far by the system is:—

$$\phi\left(\frac{1}{x+\text{KV}}\right) - \phi\left(\frac{1}{x}\right)$$

where x is indefinitely great.

Separate gas and solvent now, working both pistons so as to keep the concentrations constant, and thus arrive at the initial state, whereby in this portion of the process the system does work pv − PV.

Since the net work obtainable in a reversible isothermal cycle is zero, we have finally:—

$$pv - \text{PV} + \text{L}t_{x=\infty}\left[\phi\left(\frac{1}{x+\text{KV}}\right) - \phi\left(\frac{1}{x}\right)\right] = 0.$$

Now the term in brackets is zero if $\phi(z)$ has the form log z or any positive power of z, so that it vanishes if $\phi(z)$ has the form $a \log z + b_0 + b_1 z + b_2 z^2 +$ &c. Hence it vanishes if $\phi'(z)$ has the form $\frac{a}{z} + b_0 + b_1 z + b_2 z^2 +$ &c., since the latter series is by hypothesis convergent.

That is to say, pv = PV if the isothermal equation of state is—

$$p = \rho^2\left(\frac{a}{\rho} + b_0 + b_1\rho + b_2\rho^2 + \text{\&c.}\right),$$

or

$$p = a\rho + b_0\rho^2 + b_1\rho^3 + b_2\rho^4 + \ldots$$

This includes the equations of Boyle and Van der Waals as special cases.

The equation pv = PV is thus a formal consequence of the distribution-law and the expressibility of p as an infinite power series of ρ. However, when Boyle's law does not hold, this result loses much of its significance, as it does not then lead to an equation of state for the solution. So that this slight extension of Lord Rayleigh's result is not perhaps of much practical use.

Holywood, Co. Down. F. G. DONNAN.

The Law of Divisibility.

WITH respect to Mr. Burgess's letter in your issue of November 4, perhaps the following general rule for testing the divisibility of a given number by another, which I found some days ago, may be of some interest.

Any number

$$Z = a_n \,.\, 10^n + a_{n-1}10^{n-1} + \ldots + a_\nu 10^\nu + \ldots + a_1 \,.\, 10 + a_0$$

is divisible by another number N when the sum

$$\sum_{\nu=0}^{\nu=n-a+1}(a_{\nu-a+1} \,.\, 10^{a-1} + \ldots + a_\nu)(10^a - N)^{\frac{\nu}{a}}$$

can be divided by N without residue; otherwise the residue of this division is equal to the residue of the division Z : N.

Of course, from $(10^a - N)^{\frac{\nu}{a}}$ the nearest multiple of N must be subtracted.

Examples: (1) N = 7. Take $a = 1$; then $10^a - N = 3$, and Z is a multiple of 7 when $a_0 + 3a_1 + 2a_2 - a_3 - 3a_4 - 2a_5 + \ldots$ is divisible by 7.

(2) N = 11. $a = 1$ $10^a - N = -1$; hence Z is a multiple of 11 when $a_0 - a_1 + a_2 - a_3 + a_4 - + \dots$ is a multiple of this number.

(3) N = 103. If we take $a = 2$, we get $10^a - N = -3$, and Z will be a multiple of 103 when

$$(a_0 + 10a_1) - 3(a_2 + 10a_3) + 9(a_4 + 10a_5) - 27(a_6 + 10a_7) \\ + 81(a_8 + 10a_9) - 37(a_{10} + 10a_{11}) + - \dots$$

can be divided by 103 without residue.

To take a numerical example, try if 298744898 is a multiple of 103, and determine the residue if it is not.

We get

$$98 - 3 \times 48 + 9 \times 74 - 27 \times 98 + 81 \times 2 = -1864;\ 19 \times 103 \\ = 1957;\ \text{therefore residue} = 1957 - 1864 = 93,$$

which will be found correct by performing the division.

I have no doubt the above rule will be well known to mathematicians, but not being much acquainted with the theory of numbers, I cannot at present tell where it may be found; the proof is very easy.

C. BÖRGEN.

Wilhelmshaven, November 7.

THE examples given by Dr. Börgen, in his interesting communication, fall under suggestions (2) and (6) in my second letter, where if $\delta = 7$ the period ± 1, 3, 2 may be used; or if $\delta = 11$ the period ± 1 is available; or if $\delta = 103$ take

$$\delta_1 = \delta - a = 103 - 3$$

giving the rule—

Divide N into dual periods beginning from the units place; multiply each by $(-a)^n$, giving to n the successive values 0, 1, 2, 3 &c.: the sum of these positive and negative products is N_1.

I may add, this rule applies to $\delta = 17, 101, 103, 107, 109$, taking $a = -(2, 1, 3, 7, 9)$, or to $\delta = 19$ if $a = 5$, but if $\delta = 83$, N must be divided into triple periods, a being + 4.

HENRY T. BURGESS.

Tarporley, West Norwood, November 11.

HON. RALPH ABERCROMBY.

RALPH ABERCROMBY was born in 1842, and was the youngest son of the third Lord Abercromby. His mother was a daughter of Lord Medwyn, a Lord of Session in Edinburgh. Several of his immediate relatives had been eminently distinguished. His great-grandfather, Sir Ralph Abercromby, who died in 1801, in the moment of victory, at the Battle of Alexandria, had served his country with brilliant distinction, in the West Indies (Trinidad) and at the Helder.

As soon as the news of Sir Ralph's death reached England, and in commemoration of his services, a barony was conferred upon his widow, with remainder to his sons.

Of these sons the second became Sir John. He was in the service of the East India Company, and took the Island of Mauritius in 1810. Another was Speaker of the House of Commons in 1835, and was created Lord Dunfermline.

Ralph was never robust, even as a boy. He went to Harrow, and soon was obliged, owing to delicacy, to leave the school. He had, however, shown signs of great promise by taking a double remove after his first term.

In June 1860 he was gazetted to the 60th Rifles, and four years later obtained his lieutenancy and joined the Fourth Battalion at Quebec.

The War of Secession was then at its height. Abercromby obtained leave and visited the scene of action. He took with him letters to General Grant, and was well received, but he did not happen to be present at any of the great battles.

At the beginning of 1866 he entered the Staff College, having passed in without "cramming," but his health soon broke down there. Two visits to Kreuznach produced no benefit, and in 1869, to his great regret, he felt himself obliged to give up his commission.

In later years he twice was sent on a voyage round the world, in hopes of restoration to health; and it was in the beginning of 1890, at the commencement of a third voyage to the Pacific, that he was taken ill at Sydney—an illness which terminated fatally June 21, 1897. He passed away quietly in his sleep.

Abercromby had, from a very early period, paid much attention to observational meteorology. In his "Seas and Skies in many Latitudes," observations are recorded which he must have made during his military service in Canada. His name will live longest in connection with the new classification of clouds which he, in conjunction with Prof. Hildebrandsson, of Upsala, proposed, and which was adopted by a majority of votes at the International Meteorological Conference of Paris in September 1896.

His published books were: "Principles of Forecasting by means of Weather Charts," 1885, published by authority of the Meteorological Council; "Weather, a Popular Exposition of the Nature of Weather Changes," 1887 (International Scientific Series); "Seas and Skies in many Latitudes," 1888. In addition he brought out many papers which appeared in various journals and periodicals, such as the *Proceedings* of the Royal Society, the *Journals* of the Royal and of the Scottish Meteorological Societies, as well as in NATURE, *Good Words*, &c.

Fifteen papers are down to his name between 1873 and 1884 in the Royal Society Catalogue of Scientific Literature.

From his sick bed in Sydney he showed his great interest in the advancement of the science by making grants of money for the production of essays on meteorological subjects. Three of these have been published: "On Moving Anticyclones in the Southern Hemisphere," "On Southerly Bursters," and "On Types of Australian Weather."

Abercromby retained to the very last the power of making and keeping friends. This was in great measure due to his loyal and affectionate nature, which neither distance nor illness could impair. Those who were with him during his last suffering months bear witness to the patience and gentleness, which were as conspicuous under the trials of severe pain as they had been when he was in full possession of his faculties.

His lot was indeed a hard one. He had first to bear the heavy disappointment of enforced resignation of a profession which he loved, and in which his prospects seemed so brilliant, and then he had to sustain the strain of more than twenty years of impaired and gradually failing health.

He leaves behind him the memory of a warm unselfish friend, cut off in a distant land, far from his kith and kin.

R. H. SCOTT.

REV. SAMUEL HAUGHTON, M.D.

THE announcement of the death of Dr. Haughton has been received with the deepest regret in various scientific circles, and by his numerous personal friends and acquaintance attracted to him by his sturdy honesty, unselfishness, and geniality of disposition. He was born in Carlow in 1821. After a distinguished undergraduate career in Trinity College, Dublin, he was elected Fellow thereof in 1844. He held the Professorship of Geology from 1851 to 1881, in which latter year he was co-opted Senior Fellow of the College. He was admitted F.R.S. in 1858. The Universities of Oxford, Cambridge, and Edinburgh signified their appreciation of his merits by conferring on him the honorary degrees of D.C.L. and LL.D., respectively. Having taken the degree of M.D. in his own University in 1862, he was made Registrar of the Medical School there, and applied himself with his usual energy and activity to the reorganisation of that School; thereby raising it to its present condition of high efficiency. He was elected a Governor of Sir Patrick Dun's Hospital, which is connected with the

University, and there made his presence as beneficially felt in the management of the institution as it was in that of the School. We may take this opportunity of noting that, as the result of his experience in such work, he wrote many papers on medical subjects in various publications, and that the honorary degree of M.D. was conferred upon him by the University of Bologna. He represented the University of Dublin on the General Medical Council, from 1878 to 1896, and took a prominent and useful part in the proceedings of that body. Dr. Haughton displayed remarkable versatility of intellect. The record of his scientific work is to be found principally in his numerous papers in the publications of various scientific societies, and in scientific periodicals. We may instance those of the Royal Society, the Royal Irish Academy, the Geological Society of London (of which he was a Fellow) and that of Ireland, the Royal Dublin Society, the *Cambridge and Dublin Mathematical Journal*, NATURE, the *Philosophical Magazine*, the *Natural History Review*, the *American Journal of Science*, the British Association, &c. Among the great variety of subjects treated we may mention his discussion and calculation of the tides in the Arctic seas from the observations of voyagers, and also of the tides round the coast of Ireland, founded upon observations made under the direction of the Royal Irish Academy. He paid much attention to the granites of Ireland. A favourite subject with him was animal mechanics. It might have been better for his future name, though perhaps not for science in general, if he had bestowed his powers more on the production of *treatises* on fewer subjects. His work on the "Principles of Animal Mechanics" (London, 1873) makes us feel this. That book was the outcome of observations, experiments, and calculation extending over several years. It includes results published in various papers on different parts of the subject, contributed to the Royal Society and the Royal Irish Academy, and in lectures delivered by him before the Royal Institution in London. The important "Principle of Least Action" is brought frequently into view in his discussion of various details of the vertebrate muscular economy. A complaint, which, however, is unavoidable in this case, has been brought against this book; viz. that many anatomists would not be able to follow the mathematics, and many mathematicians would not have sufficient command of the anatomical points, there presented. His "Lectures on Physical Geography," 1880, printed in the Dublin University Press Series, are marked by his usual power and originality. We shall only allude to his "Manual of Geology," and to the numerous books on elementary science written by him and Prof. Galbraith in conjunction, some of which have had a large circulation. Trinity College, Dublin, will long mourn the vacancy left by him as a gifted son, an able administrator, and an active participator in her work of teaching. The Royal Irish Academy will feel his loss to a very special degree. He joined that body in 1845, and contributed to it most of his principal scientific papers. The Academy presented to him its Cunningham Medal, in 1848, for his "Memoir on the Equilibrium and Motion of Solid and Fluid Bodies." He was for many years a most valued member of its Council, and was President of it from 1886 to 1891. We must not forget to mention that he was for just twenty years the efficient Secretary of the Royal Zoological Society of Ireland with its Zoological Gardens, at a time when the finances of the Society were in a less satisfactory condition than at present, and it is acknowledged that, on more than one occasion, he was the means of saving the Society from shipwreck by his energy and resource. It is very rarely indeed that we meet with a man of so remarkable an individuality, and endowed with such varied powers of working in both practical and scientific lines of usefulness. C.

NOTES.

AT a meeting of the general committee of the British Association recently held, Sir W. Crookes, F.R.S., was elected President for 1898. It was decided that the meeting in Bristol shall open on September 7, 1898.

THE Executive Committee of the International Congress of Zoology, which, as has already been announced, will be held at Cambridge in August next, has recently been appointed, and is composed as follows:—President, Sir John Lubbock; Vice-Presidents, the Vice-Chancellor of the University of Cambridge, Dr. W. T. Blanford, Sir W. H. Flower, the President of the Linnean Society, Prof. Ray Lankester, Prof. A. Newton, Dr. P. L. Sclater, the President of the Entomological Society, Sir William Turner, and Lord Walsingham; Treasurers, Prof. S. J. Hickson and Dr. Sclater; Secretaries, Prof. F. Jeffrey Bell, Mr. G. C. Bourne, and Mr. A. Sedgwick; Ordinary Members, Dr. Gadow, Mr. F. D. Godman, Lieut.-Colonel Godwin-Austen, Sir G. F. Hampson, Dr. S. F. Harmer, Prof. Howes, the Hon. W. Rothschild, Mr. H. Saunders, Prof. Seeley, Dr. D. Sharp, Mr. A. E. Shipley, Prof. C. Stewart, and Dr. H. Woodward. The official address of the Congress is, by the courtesy of the Zoological Society, 3 Hanover Square, London, W.

THE interesting ceremony took place on Monday afternoon last, at the Michael Faraday Board School, Faraday Street, Walworth, of unveiling a bust of Michael Faraday. The bust, which is of white marble, was presented to the school by the managers of the Royal Institution of Great Britain, and is a copy of the original bust executed by Matthew Noble. It stands upon a pedestal of Aberdeen granite four feet in height, and has been placed in the boys' hall of the school. On the wall immediately behind the bust a large brass tablet has been affixed, bearing the following inscription:—"Michael Faraday, natural philosopher, D.C.L., F.R.S., born at Newington, Surrey, September 22, 1791. He was a patient student, an eloquent expounder, and a brilliant illustrator of the laws of nature. Fullerian Professor of Chemistry in the Royal Institution of Great Britain, 1833 to 1867. Faraday's noblest monument is his 'Experimental Researches in Electricity and Magnetism' from 1831 to 1851. He died at Hampton Court Green, August 25, 1867, and was interred in Highgate Cemetery." Sir J. Crichton Browne, F.R.S., unveiled the bust, and expressed his pleasure at being permitted to unveil this statue of a great man who had spent a long life in unveiling the hidden mysteries of nature. He hoped the sight of that bust would be an inspiration to the children, and that they would learn who Faraday was and what he did. He suggested that one day every year should be set apart in the school in memory of Faraday, when some part of his work should be explained.

PROF. OLIVER LODGE will deliver the first of a course of six Christmas lectures (specially adapted to young people) on "The Principles of the Electric Telegraph," at the Royal Institution on December 28. The remaining lectures will be given on December 30, 1897, and January 1, 4, 6, 8, 1898.

THE Jubilee Medal has been presented to Sir Robert Ball, the President of the Royal Astronomical Society.

THE Copenhagen correspondent of the *Times* states that an expedition to the Pamir regions will be fitted out next year. Its object will be to make geographical and ethnographical explorations in the northern part of the Wakhan valley. The expedition will be under the leadership of Lieut. Olufsen, and will include two scientific experts. Its cost will be partly borne by the Danish Government out of the Carlsberg fund, and the explorers expect to be absent for two years.

Science announces that the Austrian steamship *Pola* has again gone to the Red Sea for scientific explorations, and will this year cover the ground between Dschedda and Aden. Dr. Franz Steindachner, the ichthyologist, has charge of the zoological work, and observations will also be made in physical oceanography.

THE meeting of the American Psychological Association will be held this year at Cornell University, Ithaca, under the presidency of Prof. Baldwin, the sessions beginning on December 28.

ACCORDING to the Allahabad *Pioneer Mail*, the Ceylon Survey Department is about to start on a cadastral survey of the Crown lands and lands of doubtful ownership in the island, on a scale of ten inches to the mile, and a topographical survey on a scale of one inch to the mile. It is estimated that the cadastral survey will occupy the ordinary staff for about twenty-five years. The triangulation and topographical survey, which will embrace the whole island, will, it is expected, be completed in five or six years. It is stated that at the present time there is no trustworthy map of Ceylon in existence; that there is no contour map of the island of any description, and that the present so-called map is a compilation from Colonel Fraser's map (now nearly 100 years old), and contains errors so numerous and gross as to make it useless. Hence the new surveys to which reference is made.

THE Indian Section of the Pasteur International Memorial Fund has just forwarded a further contribution to the above of 17*l*. 3*s*. 6*d*., bringing the total amount subscribed in India up to the handsome sum of 460*l*. In a letter to Prof. Percy Frankland, F.R.S., Surgeon Major-General Cleghorn mentions that "the original subscription list contains the names of a goodly number of natives who have subscribed small sums."

WE are glad to notice that Surgeon-Major A. M. Davis is to be attached to the office of the Principal Medical Officer in India, as a tentative measure, for one year, for the purpose of carrying out bacteriological and sanitary investigations. We hope the office of bacteriologist and sanitary investigator will soon be a permanent one. It is also stated that the Madras Government has applied to the supreme Government for the appointment of a bacteriologist, and has received a sympathetic answer, the suggestion of the Government of India being that the present Professor of Hygiene at the Medical College should be appointed Professor of Bacteriology.

FURTHER particulars of the arrangements for the forthcoming meeting of the Australasian Association have reached us. Sir James Hector, the president of the geographical section, has announced as the probable subject of his presidential address—"Submarine Geography," and that the title of his popular lecture will be "Antarctica and the Islands of the Far South." A lecture to working men will be given by Prof. Threlfall and Mr. J. A. Pollock, who will speak on "Electric Signalling without Wires." The following papers, in addition to those already noted in NATURE, have been promised:—"On the Magnetic Force, at Right Angles to the Axis in the Interior of Solenoids," by C. Coleridge Farr; "The Work of High Level Stations in Australasia, with special reference to Mount Kosciusko and Mount Wellington," by Clement L. Wragge; "Milk Analysis in its relation to the Butter and Cheese Industries," by H. W. Potts; "Suggestions for a New Classification of the Eucalyptus," by Prof. Ralph Tate; "On the Occurrence of *Eucalyptus pulverulenta* in Victoria," by A. W. Howitt; "Notes on the Flora of the Mallee Districts of Victoria," by St. Elroy D'Alton; "On the Growth of Galls and Gall Insects," by W. W. Froggatt; "Notes on the Disappearance of Native Races in general, and of Fijians in particular," by H. H. Thiele; "The Colour of Flowers, and its Influence on Bee Life," by Albert Gale; "Notes on the Wax of *Ceroplastes rubens*," and "On the Colouring Matter of *Eris cocci eucalypti*," by E. H. Gurney. A long list of excursions has been prepared, and at a recent meeting of the Council it was unanimously decided that scientific societies in other colonies should be invited to send non-resident delegates to the Sydney session; and that members of the British, American and foreign associations, non-resident in Australasia, who attend, should be admitted free.

THE following science lectures will be delivered at the Imperial Institute on the dates mentioned:—On November 19, "Three Years in the Arctic," by Mr. F. G. Jackson; on November 22, "Electric Balloon Signalling applied to Scientific Exploration in Arctic and Antarctic Expeditions," by Mr. Eric Bruce; on November 29, "The Wild Kafirs of the Hindu Kush," by Sir G. S. Robertson; on December 6, "The Mineral Resources of British Columbia and the Yukon," by Mr. A. J. McMillan; on December 13, "Canada's Metals," by Prof. W. C. Roberts-Austen; on December 20, "The Petroleum Sources of the British Empire," by Mr. Boverton Redwood.

THE International Congress on the Protection of Birds, opened at Aix-en-Provence on November 9, and arranged by the Ligue Ornithophile Française, of which M. Louis-Adrien Levat is the president, was concluded on Saturday last. The protection of insectivorous birds useful to agriculture was the chief matter discussed, and it was decided to forward to the Governments of Europe, through the French Minister of Foreign Affairs, the resolutions which were formulated. Public educational bodies are also to be approached in order to obtain, if possible, the serious consideration of this important subject by schoolmasters and Government school inspectors. Numerous French and Italian agricultural, horticultural, and sporting societies were represented at the Congress, and delegates from the Selborne Society and the Society for the Protection of Birds were also present.

THE late Mr. W. Bolitho of Penzance, for thirty-five years treasurer of the Royal Geological Society of Cornwall, bequeathed 500*l*. to the trustees of that Society, the yearly income accruing from which was to be applied to the purchase of a gold medal, "to be called the William Bolitho Medal, to be awarded to such member of the said Society, whether Ordinary, Honorary, or Associate, whose attainments, labours, and discoveries in Geological or Mineralogical Science shall, in the opinion of the President and Council of the said Society, best deserve recognition." The first award of this medal was made in November, 1896, to Prof. Robert Etheridge, in recognition of "his age, his great attainments, and his life-long labours for the benefit of science." The second award was made on the 9th inst. to Mr. Howard Fox, of Falmouth, in recognition of his various discoveries in the field geology of Cornwall, and of his having brought to light the radiolarian beds of the south-west of England.

THE *Electrical World* (New York) states that the National Museum at Washington has just been enriched by a very valuable and interesting collection, comprising the private papers of the late Mr. Cyrus W. Field relating to the laying of the first Atlantic cable, cable despatches first sent, objects with which Mr. Field worked out the idea of laying the cable, and many other things of interest pertaining to the project. The correspondence and autograph copies of telegrams sent by Mr. Field to the President of the United States and other eminent persons are included. The globe, which was constructed in London, and on which Mr. Field traced the course of the cable to be laid from Newfoundland to Ireland, forms an attractive object of the collection. It is about 18 inches in diameter, on a stand, with a magnetic compass underneath, and shows many signs of hard usage. The journal kept by Mr. Field and notes of deep-sea soundings set down by him and officers of the *Great Eastern*, which laid the cable, are part of the collection. Mr. Field's private library, with all the literature relating to the work of laying the cable, forms another part. There are also copies of medals presented to Mr. Field by Congress and the French Government, engrossed resolutions passed by public bodies in the United States and in Europe, a cane from the wood of the *Great Eastern*, &c., as well as cases containing sections of the first Atlantic cable.

The Paris correspondent of the *Times* gives particulars of the trial trip at Mantes of the electric locomotive devised by M. Heilmann. The train, which was composed of twelve carriages and a luggage van, and carried 250 persons, weighed about 150 tons. The object of the trip was not to make a trial of speed, and the train journeyed at the rate of only eighteen miles an hour; the experiment seems, however, to have been considered a great success, and testimony is borne to the ease and regularity of the movement of the train. Great things are hoped from this invention, no less than the conveying of a train weighing 300 tons at the speed of sixty-two miles an hour being looked forward to. The Heilmann engine draws a closed tender containing a steam engine of the Pilon pattern, which works the dynamos producing electricity. The motive power is transmitted directly to the eight wheels, which are only one metre five centimetres in diameter. The consumption of coal by the engine is less than that of an ordinary engine, so that the locomotive can go greater distances with fewer and shorter stops for replenishing coal and water. It will, of course, light up the carriages by electricity, and it is thought that the electric will supersede the air brake.

A lecture on "Microscopic Observations on Deterioration by Fatigue in Steel Rails," was given on Monday, the 8th inst., before the Sheffield Society of Engineers and Metallurgists, by Mr. Thomas Andrews, and is reported in the *Sheffield Daily Telegraph*, from which we give a condensed report as follows:—The earlier part of the lecture was occupied with the consideration of the external stress and disintegrating forces imposed on rails, and a large number of illustrations of the state of the wearing faces of rails which had endured the stress of wear for known periods and under known conditions of main line service were given. The gradual development of lines of transverse weakness, indicating the danger from minute cracks, and showing the influences of internal micro flaws in assisting the loss of strength due to vibratory stress were then traced. The effects also of varied chemical compositions on the physical properties and strength of steel rails were also considered, and illustrated by numerous micro-sections and micrographs. The lecturer referred to his recent researches on another serious cause of the loss of strength in rails arising from occasional segregation of the chemical constituents and impurities in steel rails, and offered suggestions for the prevention of this evil. He further referred to the light thrown on this question by recent microscopic researches on the structure of gold and other metallic alloys. The effects of the secondary crystallisation of iron recently observed by the lecturer were also illustrated. Reasoning from the results of his research on the microscopic structure, chemical composition, and physical structure of rails of satisfactory long life, Mr. Andrews indicated the conclusions he had arrived at as to the specification for modern rails best calculated to ensure durability and safety for main line services. The lecturer mentioned that he was still pursuing additional chemical, physical, and microscopical researches on the important question on the loss of strength in steel rails by reason of use, and expressed the hope that valuable results in the interests of the public safety would result.

At a meeting of the Nottingham Naturalists' Society on November 9, the newly-elected president, the Rev. A. Thornley, delivered a thoughtful address on "The Work of a Natural History Society." In the opinion of the president, the functions of a Society such as theirs should embrace at least the following objects: instruction, stimulation, field-work, and protection. The speaker, in the course of his remarks, regretted that the study of entomology has up to the present been to a large extent neglected in the county of Nottingham, but stated there were signs of improvement in this direction, as during the past year their Coleoptera list had been largely augmented by the labours of several members of their Society.

The so-called "fruit cure," although not much heard of in this country, is well recognised at various places on the continent, where so-called grape-cure stations have been established. In a recent number of *Modern Medicine and Bacteriological Review* there is an interesting article on the subject, in which the historical side of the question is dealt with. Thus we are told that many medical authorities in the tenth century become enthusiastic in their writings over the remarkable curative virtues of grapes, whilst a certain Van Swieten, of a more modern date, is said to have "recommended in special cases the eating of twenty pounds of strawberries a day." The same gentleman also reports a case of phthisis healed by strawberries, and cites cases in which maniacs have regained their reason by the exclusive use of cherries as food! These instances rather savour of the miraculous; but there is no doubt that the so-called grape-cure, for indigestion and other evils, is carried on in many places on the continent, and that people betake themselves to Meran, Vevey, Bingen, or to Italy and the South of France with the intention of devoting six weeks to the cure, during which time they are expected to have gradually accomplished the feat of consuming from three to eight pounds of grapes daily as the case may be. Grapes are said to exercise a salutary action on the nervous system and to favour the formation of fat, that is to say, when fruit of good quality is employed; if the grapes are not sufficiently ripe, and are watery and sour, the patient may lose rather than gain in weight. Dr. Kellogg, Director of the Sanitarium Hospital and Laboratory of Hygiene at Battle Creek, Mich., is of opinion that the valuable results obtained by a fruit diet in cases of biliousness which he has observed are due to the fact that noxious germs habitually present in the alimentary canal do not thrive in fruit juices.

The Board of Trade report for 1897 on the sight tests used in the mercantile marine shows that of the fifty-six candidates who failed in colour vision in 1896 twelve were examined on appeal, of whom five passed and seven were rejected. The number of officers already in possession of certificates who, on coming up for examination in 1896, failed to pass the sight tests, was twelve—one master, five mates, and two second mates failing in colour vision, and one mate and three second mates failing in form vision. Two of the mates who failed in colour vision appealed and passed, and one of the second mates who failed in form vision passed on re-examination. The percentage of failures to pass the colour tests was 1·02, a percentage almost exactly the same as that obtained in former years, before the introduction of the wool test. The most extraordinary point in the report is the great number of normal-sighted persons who were rejected as colour blind; no less than 41·6 per cent. of those who appealed passed. This state of things, says the *British Medical Journal*, we may expect to continue until properly qualified medical men are employed as examiners, and a trustworthy test is used.

The Königsberg and Memel district of East Prussia is known to be a district in which ophthalmia is prevalent. According to the *British Medical Journal* a careful examination of the eyes of all children in schools at Königsberg has just been carried out by twenty-seven doctors, the result showing that 32 per cent. of the children are suffering from ophthalmia, and of these more than a third from granular lids.

From the U.S. *Monthly Weather Review* for August we learn that the Postal Telegraph Cable Company is co-operating with the United States Time and Weather Service Company of New York in establishing throughout the city a number of handsome clocks which shall exhibit standard time, not only by the face of the clock, but by the dropping of a time-ball at noon. Under the dials are panels, which are filled up partly by special advertisements, and partly by the latest Weather Bureau reports and forecasts, which are thus made known two or three hours before they appear in the afternoon papers. The stands contain, in addition, a barometer and thermometer. The clocks have also been erected in many western cities, and the arrangement is somewhat similar to the so-called Urania Columns in Berlin, where they are said to be very popular.

The *Indian Daily News* for October 23 contains a preliminary note on the Calcutta earthquake of June 12, by Prof. F. Omori, who has been making investigations on behalf of the Japanese Government. One peculiarity of the earthquake is that, notwithstanding its vast area of disturbance, the motion on the surface was not extremely violent. The variation of the intensity of the shock along lines across the seismic area was very gradual, and from this Prof. Omori infers that the depth of the seismic focus was not less than twenty miles. The shock appears to have been strongest at Shillong, Cheerapoonjee, and the neighbouring district. At Shillong the acceleration was calculated from overturned bodies to be about 8 feet per sec. per sec.; and this, if the period of vibration were one second, would imply a range of motion (or double amplitude) of about 5 inches. Prof. Omori believes that the origin of the earthquake was a sudden splitting asunder of the strata at a great depth, caused by an injection of steam or gas into cracks in the earth's crust. The seismic focus was situated in an east and west direction under the Garo and Khasi Hills, and to the west or north-west of the centre of the great Cachar earthquake of 1869.

A new form of electric seismoscope is described by Dr. G. Agamennone in the last *Bollettino* of the Italian Seismological Society, the chief merits claimed for it by its inventor being its comparatively slight cost (about thirty francs) and its great sensitiveness. In most seismoscopes the movement of a pendulum is magnified by a long pointer, whose tip just passes through a hole in a metal plate, contact with which completes an electric circuit and starts a clock previously set at twelve. In the new instrument the metal plate is not, as usual, fixed, but is connected with a second inverted pendulum, the bob of which is near the top of its supporting rod, while that of the first is near the base.

We have received from the Imperial Observatory of Constantinople the monthly bulletins for January and February of the present year. They contain a brief meteorological summary, and continue, though apparently in less detail, the valuable lists of earthquakes issued for the years 1895 and 1896 by Dr. Agamennone. Both parts are the work of the Director, M. Salik Zéky.

An automatic controller, intended for checking the issue of tickets in a railway booking-office, has been recently exhibited in London. The machine, which is of Belgian origin, is so arranged that each ticket is printed as issued. By two movements the clerk prints on the ticket the name of the issuing office, the destination of the passenger, the class, number, month, day, and hour of issue, and the serial number of the ticket. At the same time a record of the issue is printed on a slip of paper, which is inaccessible to the issuing clerk, and serves for making up the books at the end of the day, or other convenient opportunity. The names of the stations are arranged round the edge of a disc forming part of the machine, and in issuing a ticket, the clerk sets the name of the station required opposite a fixed mark. A downward movement of a small handle, of which there are a number corresponding to the different classes, causes an electric motor to do the necessary printing and eject the printed ticket from the machine. It is stated that each machine can be made to suit any number of stations up to 100. Where a larger number have to be dealt with, extra machines would be employed. A practical trial of the instrument, is, we understand, to be made on the Northern Railway of France in connection with the suburban service. Where large numbers of stations have to be dealt with, the inventor proposes to modify the arrangement of his machine by fitting it with keys like a typewriter, the depression of any one of which will cause the printing of a ticket for the corresponding station. In this way a possible loss of time in selecting the proper station from the rim of the disc previously referred to will be avoided. The machine, as made for twenty stations, is about 5 feet 8 inches high, and has a base 18 inches square.

The U.S. Pilot Chart of the North Pacific Ocean for the present month contains, among other useful information, a description of the storm-warning signals employed by the various maritime nations. In looking over this list one is struck by the great success of the system of drum and cone signals introduced in this country in the year 1861 by Admiral FitzRoy, the first chief of the Meteorological Office, as these have been adopted, in either their original or somewhat modified form, in every European country in which storm signals are used except Portugal, which uses flags only; while in France, Germany and the Netherlands the cones or drums are supplemented by the use of flags or balls. They are also used in India and Japan in conjunction with balls, while flags or balls (only) are used in China and in North and South America. Prior to their introduction by Admiral FitzRoy, no signals to give notice of possible atmospherical disturbances were employed except in Holland, where there was a kind of semaphore, showing the difference of barometric readings between two places, from which one's own conclusions could be drawn as to the probability of approaching bad weather.

With the notable exception of M. Pénaud, most experimenters on mechanical flight have worked with fixed aeroplanes driven by a screw-propeller. A somewhat new departure has been made by Major R. F. Moore, who has selected the Indian flying-fox (*Pteropus edulis*) as his pattern on which to construct models. From his experiments, which are described in the *Aeronautical Journal*, Major Moore concludes that artificial wings can be constructed in imitation of those of the flying-fox, and that the action of the pectoral muscles can be reproduced by spiral springs of suitable strength to hold the wings expanded, the up and down motion being accomplished by means of a light electric or other motor. Two or more pairs of wings, arranged tandem fashion, are found to be better than a single pair—a result fully in accordance with the conclusions formed by other observers. Major Moore considers it quite possible to construct a machine of this type capable of raising a man.

One of the most remarkable papers read at the recent annual meeting of the Botanical Society of America in Toronto was on the discovery of antherozoids in *Zamia*, by Mr. H. J. Webber. The paper has been printed at length in the *Botanical Gazette*, and, after the discovery of a similar mode of fertilisation in *Cycas* and *Salisburia*, will attract great attention. In *Zamia integrifolia* Mr. Webber states that there are formed, within the pollen-tube, near its basal end, two cells, one in advance of the other. From each of the cells thus formed is developed a motile antherozoid, two to each pollen-tube. They are of a much larger size than any known in vascular cryptogams, quite visible to the naked eye, and resemble in general structure those of ferns. The mature antherozoid passes into the archegone through an opening at the apex of the pollen-tube, and the fluid in which it swims about is supplied by the watery contents of the pollen-tube. The nucleus of the antherozoid is very large, and is surrounded on all sides by a thin layer of cytoplasm. The antherozoids rotate, the cilia continuing to oscillate for a considerable period after the rotation has ceased.

The *American Naturalist* for October contains a short memoir and a photograph of Mr. J. E. Humphrey, the botanist, whose untimely death from malarial fever while on a scientific expedition to Jamaica we recently recorded. Born in 1861, at Weymouth, Mass., he took up the study of botany from his student-days. Immediately after graduation he was appointed assistant in the botanical laboratory at Harvard, under Prof. Goodale. In 1887 he was selected as instructor in botany in the University of Indiana, and in 1888 botanist to the State Agricultural Experiment Station at Amherst, Mass. From 1892 to 1894 he studied under Prof. Strasburger at Bonn, and on his return was appointed lecturer on botany to the Johns Hopkins University at Baltimore. His best-known work was in connection with the diseases caused in plants by parasitic fungi.

A monument to the great anatomist Malpighi was unveiled on September 8, in his native town of Crevalcore.

The last number of the *Proceedings* of the Zoological Society includes two papers which form important additions to the knowledge of the land fauna of Spitsbergen. The collections described were formed during Sir Martin Conway's expedition by Dr. J. W. Gregory. The first paper is by Mr. D. J. Scourfield, and describes the Rhizopoda, Tardigrada and Entomostraca The Rhizopoda include twenty-one species, all of which have a wide distribution in space, but are all new to the Spitsbergen fauna. In several species, especially *Euglypha ciliata* and *Nebela collaris*, the shells are abnormal in shape, which Mr. Scourfield suggests may be due to the severity of the climate under which they live, for the specimens of *Cyclops* collected are also abnormal. Among the Tardigrada four species are described, of which one, *Echiniscus spitsbergensis*, is new. Only one Water-bear has been previously recorded from Spitsbergen; it was described by Goes in 1862 as an ally of *Macrobiotus dujardini*. Two species of Acarina are recorded, both additions to the Spitsbergen fauna, as are also the two species of Copepoda.

A second paper, by Mr. David Bryce, deals with the Rotifera Previously the only records of members of this group from Spitsbergen were the mention of two indeterminable species by Goes in 1862, and the identification of one species (*Callidina alpium*) by Ehrenberg in 1869. Mr. Bryce's paper adds twenty-five more species belonging to ten genera. Two of the species (*Stephanops tenellus* and *Callidina venusta*) are new. The commonest species collected was *Callidina plicata*. The previously known species are North European in range: some of them are very rare; one *Callidina cornigera* has been previously known only by two single specimens. Bergendal has recorded eighty-two species of Rotifera from Greenland, but from a latitude about 700 miles further south than the Spitsbergen specimens were collected; and of the Greenland species only three were collected in Spitsbergen.

The number of investigations in physiology and the allied sciences now made in the United States of America having become so numerous, it has been thought that the present means of publication need supplementing; hence it has been decided to start in January next a special journal, entitled *The American Journal of Physiology*, to meet the needs of investigators in physiology, physiological chemistry, physiological pharmacology, and certain other branches of biology. Each volume, which will be edited for the American Physiological Society by an influential board of seven doctors, will contain about five hundred pages, divided into parts or numbers, to be issued whenever enough material has been received. The promoters are not very sanguine as to the financial success of their enterprise—at any rate, for some time to come; and they, therefore, solicit the aid of all friends of learning until the journal shall be established on a self-supporting basis. The yearly subscription price for the British Isles is a guinea, and subscriptions should be sent to Dr. W. T. Porter, 688 Boylston Street, Boston, Mass., U.S.A.

We offer our congratulations to our contemporary the *Electrical Review*, which, with its current issue, completes the twenty-fifth year of its existence. This event is celebrated in a fitting manner by the publication of a number of articles by specialists dealing with the progress made in the various departments of physical science during the time the *Electrical Review* has been in circulation. Our space is too limited to enumerate even the titles of the special contributions to this number; it must suffice for us to say that a vast amount of information is given in a very condensed form, the perusal of which is certain to interest all physicists.

Dr. Donald MacAlister, of Cambridge, has, with the assistance of Prof. Cattell, of the University of Pennsylvania, just completed a thorough revision of the second part (Sections ix.-xv.) of his English translation of Ziegler's "Text-book of Special Pathological Anatomy." This announcement will be welcome to many students of the subject, as the book has been inaccessible for some time past. The new part will be published in the course of a few weeks by Messrs. Macmillan and Co., Ltd.

We have received from Messrs. George Newnes, Ltd., the first part of the serial issue of Nansen's "Farthest North," which is being brought out in this popular form by arrangement with the original publishers of the work. The book will be completed in twenty fortnightly parts.—From the same publishers also comes the November number of the *Strand Magazine*, which, as usual, contains one or two articles treating of science in a popular manner. In the number before us Mr. Grant Allen writes pleasantly on "Marriage among the Clovers," and certain "Pests" are written about by Mr. Warren Cooper. Two of the pests in question, viz. "The Jack Rabbits of the United States," and "The Water Hyacinth of the St. John's River, Florida," have already received notice in the columns of Nature (vol. liii. p. 586, and vol. lvi. p. 332).

The additions to the Zoological Society's Gardens during the past week include a Whooper Swan (*Cygnus musicus*), a Night Heron (*Nycticorax griseus*), European, presented by Mr. W. H. St. Quintin; a Californian Quail (*Callipepla californica*) from California, presented by Mr. Walter Robertson; a Gannet (*Sula bassana*), British, presented by the Rev. G. H. Thompson; a Dwarf Chameleon (*Chamaeleon pumilus*) from South Africa, presented by Mrs. Wolterbuk; a Common Seal (*Phoca vitulina*), British, deposited; a Rosy-billed Duck (*Metopiana peposaca*), three Anomalous Snakes (*Rhadinaea anomala*) from South America,, two Golden Plovers (*Charadrius pluvialis*), two Dunlins (*Tringa alpina*), four Common Gulls (*Larus canus*), British, purchased; three Himalayan Monauls (*Lophophorus impeyanus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE NOVEMBER METEORS (LEONIDS).—Although it was known that the presence of the moon would hinder materially the brilliancy of the display of the members of this particular meteor swarm, many hoped that the weather at least would compensate us for that of last year. We were, however, doomed to disappointment, and clouds were the order of the night, both in London and in many other counties where observers were on the watch. Mr. Denning, writing from Bristol on the 15th, observes lamentably, ". . . up to the present time my results are negative. November 12 was cloudy all night, November 13 cloudy, except for an interval of partly clear sky between 11h. 30m. and 14h., and November 14 overcast all night."

Saturday night (November 13) in London proved really a first-class night for such observations, excepting, of course, the presence of the moon. It is true that white fleecy clouds occasionally came rolling up from the southward, but they afforded a magnificent spectacle, and soon disappeared in the north, leaving the sky brilliantly clear. Three facts were impressed on one when watching the heavens: first, the dearth of meteors; second, the great number of stars visible considering the brightness of the moon; and third, the extreme mildness and absence of dew.

In a watch lasting more or less continuously from 9h. to 17h. o'clock, only twenty meteors were seen, fourteen of these being estimated as Leonids, three Andromedes, and two Lyrids.

The five most brilliant Leonids were plotted directly on a star chart (Mean Equinox 1870). Three of these, when their trails were prolonged backwards, converged nearly to a point giving the coordinates of the radiant point as 152°, + 25°, while the other two apparently emanated from 171°, + 19°. The details of each are as follows:—

No.	G.M. Time	Coords. of commencement		Coords. of end		Colour	Remarks
	h. m.	°	°	°	°		
1	13 50	177	+ 4	187	− 18	Yellowish	Very quick
2	14 10	184	+26	197	+39·4	—	"
3	14 50	143·4	+22	123·4	+ 13	Yellow-blue	"
4	15 30	156	+35	161	+ 45	—	"
5	15 55	166	+11	182	− 8·9	Reddish tinge	Very slow, nucleus, very wavy trail near head just before disappearance

Number 5 was somewhat unusual, falling towards the south-eastern horizon very slowly, that part of the trail close to the head being distinctly wavy. It may be mentioned that two cameras pointed first towards the Pleiades in the earlier portion of the evening, and towards Leo when sufficiently high in the sky, recorded not a single trail, although fourteen plates were exposed for forty minutes each during the time of observation.

JUPITER'S THIRD AND FOURTH SATELLITES.—Prof. Barnard has communicated to the *Astr. Nach.* (No. 3453) some most interesting observations of the third and fourth satellites of Jupiter, together with a set of drawings of these bodies made both out of and at the time of transit. These observations are valuable, as they can be compared with those made by Mr. Douglass, and described in the *Astr. Nach.* (No. 3432). That they differ from these latter is only natural considering the difficulty of the observations themselves, but that this difference is so great and fundamental is very surprising. Mr. Douglass, it will be remembered, found that the surfaces of these two satellites were covered with series of fine dark lines, measuring less than 0″·1, or about 200 miles, and similar somewhat to those surface markings as observed at his observatory upon Mars, Venus, and Mercury. Prof. Barnard, on the other hand, has failed altogether to see these details, although he has employed the 36-inch Lick refractor in the attempt; the markings he observed always appeared to be large and more or less diffused, with the exception of the white polar caps which, as he says, are exactly like those of Mars. In the case of the third satellite the cap is generally situated at the north limb, although on one or two occasions a white southern cap has been observed. Both caps of the fourth satellite have been clearly distinguished, that at the north being sometimes exceptionally large, covering a surface equal to one-quarter to one-third of the diameter of the satellite.

Most interesting are the appearances and apparent changes of form which these satellites undergo when in transit. Thus, as regards the third satellite the transit "was very remarkable. The satellite appeared as a black or very dark spot on its disc, and close to the south limb of the satellite was a small, round, very white spot, fully as conspicuous as I have shown it. No other details were seen on it." The drawing referred to above shows the satellite's disc very nearly black, the spot measuring about one-sixth of the diameter of the satellite being represented nearly white. The observations of Prof. Barnard show fairly conclusively that the changes in form of the discs as they pass across the primary are only apparent, and not due to any peculiarity of shape of the satellites themselves. In fact, he himself is perfectly convinced that they are caused by the relative intensities of the satellite's markings in their transit over those of the primary. The peculiar feature of a double dark spot, or an elongated white spot shown by the first satellite in transit, is due to the fact that this body has a bright equatorial region and dark poles. When transiting across a bright portion of Jupiter's disc, the satellite appears like a double dark spot, and when over a dark portion like an elongated white one.

The discrepancy between the forms of the surface markings on these satellites, as seen by two such observers as Mr. Douglass and Prof. Barnard, is indeed remarkable, and it would be of interest to know what would be the result of an interchange of instruments at the time of the next oppositions.

COMET PERRINE (OCTOBER 16).—The following is a continuation of the ephemeris of Comet Perrine for the ensuing week as computed by Herr. J. Möller (*Astr. Nachr.*, No. 3456):—

12h. Berlin M.T.

1897.	R.A.	Decl.	log *r*.	log Δ.	Br.

THE VARIABLE STAR β LYRÆ.—If Argelander's formula be used for the determination of the times of minima and maxima of this variable star, it will be found that these times do not exactly correspond with those now observed. Herr Pannekoek has recently undertaken to investigate the cause of this discrepancy, and has published his results in the *Koninklyke Akademie van Wetenschappen te Amsterdam* (vol. v. No. 7). A brief account of the main results are, however, contributed to the *Astronomische Nachrichten* (No. 3546). The improved formula for determining the times of the principal minima is given by Herr Pannekoek as

$$\begin{aligned}&1855 \text{ Jan. } 6, 604 \text{ Greenwich M.T.} + 12{\cdot}908009\,E\\&\quad + 0{\cdot}000003855\,E^2 - 0{\cdot}000000000047\,E^3,\end{aligned}$$

and he adds a table, which facilitates greatly this computation, containing every twentieth minimum from E = − 500 (1837) to E = + 1500 (1908).

To determine the amount, if any, of a variation in the light curve, Herr Pannekoek divided the period of observation into two parts, before and after 1870, and obtained two sets of mean values for the mantissæ of the principal points reckoned from a principal minimum:

	1st max.	2nd min.	2nd max.
	d.	d.	d.
1842–1870	3·12	6·40	9·54
1870–1895	3·32	6·48	9·73

This showed that the difference between the intervals from the principal minimum in the case of the maxima was quite apparent, while in the case of the secondary minimum it was comparatively small. It is pointed out, however, that a possible cause may be due to different methods of curve-drawing, some observers drawing the curves symmetrically, and others not. The curves, he finds, further show small irregularities in intensity somewhat of the same kind as those observed in η Aquilæ, which render uncertain the times of first maximum and principal minimum. Herr Pannekoek finds that only the variation in the time of the maxima can be put down to causes other than those of errors of observation and drawing.

GEOLOGISTS IN CANADA.

IN recording in our columns the proceedings of the British Association at Toronto last August, passing reference was made to the excursion to the Pacific coast which was to take place at the close of the meeting. This excursion was in every way such an unqualified success, and especially from the point of view of the geologist, that we think some further account will be acceptable to British geologists who were unable to attend the meeting.

It was indeed a tour which could not but make a lasting impression upon all of us who took part in it. The vast extent and diversity of the country traversed; the richness of the material resources of the Dominion of Canada; the energy and enterprise of its inhabitants; the orderly conditions of the new civilisation even in the remotest settlements, were features which could only be properly appreciated after an experience of this kind. And beyond these general impressions it was scarcely possible for the student of any branch of science to traverse the great continent without accumulating fresh material and fresh ideas in his own particular subject. Amid a panorama of scenery always interesting and sometimes magnificent, we were carried from ocean to ocean in the greatest comfort, in many parts of the course through stretches of mountain and forest which but for the railway would have been absolutely impenetrable for the traveller however well equipped.

The arrangements for the excursion were made by the Local Committee in Toronto, who invited a limited number of the visiting members of the British Association to take part in it. To these members the Canadian Pacific Railway Company munificently presented tickets for the whole length of their main line, with the privilege also to travel without cost over any of their branch lines. A special car was attached to each of the west-bound trains leaving Toronto on three consecutive days, and remained at the service of the members until they reached the Pacific coast. The excursion party thus resolved itself into three groups, which were so arranged by the Local Committee that those of like interests should as far as possible travel together.

The geologists and their friends the geographers formed the third of these groups, leaving Toronto in the sleeping car "Chaudière" on the noon of Friday, August 27. They were especially fortunate in having for their leaders Dr. G. M. Dawson, the Director of the Canadian Survey, and Prof. A. P. Coleman, of the Toronto University and the Bureau of Mines of Ontario, men whose knowledge of the country to be traversed was so intimate that no point of interest could escape unnoticed. Among the members of our party were Dr. W. T. Blanford, Prof. W. C. Roberts-Austen, Dr. C. Le Neve Foster, Prof. Albrecht Penck (of Vienna), Prof. W. M. Davis (of Harvard), Prof. K. Huerthle (of Breslau), Sir George Robertson, Prince Kropotkin, Prof. H. E. Armstrong, Colonel F. Bailey, Prof. T. Hudson Beare, Dr. H. O. Forbes, Mr. W. E. Hoyle, Dr. A. Harden, Dr. J. Scott Keltie, Mr. G. W. Lamplugh, Dr. H. R. Mill, and Prof. H. A. Miers.

From the very outset the geological interest of the journey was continuous. Scarcely had we left Toronto when Prof. Coleman pointed out to us the long stretches of the Iroquois beach, an ancient tilted shore-line of Lake Ontario. Next we passed for three or four hours over an irregular plain of drift, beneath which lay hidden the almost undisturbed Palæozoic rocks of this region. After skirting the shores of Lake Simcoe, we crossed the great unconformity, and found ourselves upon that vast Archæan protaxis which was thenceforward to be traversed for a distance of over 1100 miles almost without interruption. Night closed on the characteristic scenery of this Archæan country—a timbered wilderness with hummocky rocks, everywhere smoothed and polished by glaciation, rising into low hills and enclosing lakes and lakelets innumerable with swamps or sluggish drainage channels between. Lake Nipissing, with its ancient terraces, through which it is believed that the outflow of the Upper Great Lakes once found its way into the Ottawa River, was passed in the night. In the morning we found ourselves "side-tracked" at Sudbury, in the centre of a mining region, which already produces fully one-half of the world's consumption of nickel, and could supply more.

With that energetic hospitality which met us at every halt, the Mayor of Sudbury, with a local committee of reception, was early astir with a carefully arranged plan for the day. After a public breakfast a special engine was at hand to take the "Chaudière" and its occupants to the renowned Copper Cliff Mines. Through the admirable forethought of Dr. Dawson, who struck something akin to awe into us by his power of conjuring up in the most unlikely places whoever or whatever we might most desire, Mr. A. E. Barlow, of the Canadian Survey, had made his appearance on the train during the night from his camp in the woods, and was ready to give us the benefit of his intimate knowledge of the district. With him and Prof. Coleman as our guides, we studied to the best advantage at the outcrop, the mode of occurrence of these great deposits of nickeliferous pyrrhotite and chalcopyrite which apparently are segregated in an area of gabbro near its contact with granite. We were then shown through the surface works of the mine, the managers pointing out to us each stage in the reduction of the ore, from its initial crushing and roasting to its smelting into "matte," in which form it is sent east for further refinement. Some of these processes were especially interesting to the metallurgists and chemists of our party.

On leaving this mine we divided into two companies, those who were anxious to see more of the nickel-mines visiting Denison, about twenty miles west of Sudbury, where the prospectors were developing an ore-deposit similar in character to that of Sudbury, but remarkable as containing also some platinum in the form of the rare arsenide, sperrylite, and a little gold. Here some of the earth overlying the ore-deposit was panned out, and a fair show of grains of sperrylite obtained.

The other members were conveyed by their special engine to Fairbank, a few miles distant, whence they went in wagons over a terribly rough "corduroy" road to a place in the woods where a curious vein of carbonaceous material had been struck, which its discoverers hoped might prove a valuable source of fuel. This material, known as anthraxolite, though not a true coal in the ordinary sense, is composed of almost pure carbon. It occurs in this place as an irregular upright vein, in some parts several feet in width, somewhat interpenetrated by quartz. This vein cuts across the bedding of the surrounding dark carbonaceous slaty rocks, which are either of Lower Cambrian or of Huronian age.

At this place, as we wound our way along the forest trail towards the luncheon place, there was a sudden and for the moment inexplicable stampede of the foremost members of the file, who had unwittingly plunged into a hornet's nest, and suffered inconvenience in consequence. And this little accident was the only mishap of the whole journey!

After luncheon a further expedition was made in birch-bark canoes up the Vermilion River, for three or four miles, to a spot on Vermilion Lake where a shaft had been sunk to develop another vein of the anthraxolite, but where its mode of occurrence was not so clearly seen. On regaining our vehicles, we were conscious on starting of a sense of loss, and then perceived that our two most prominent foreign members were missing. We discovered them, however, placidly eating pie in the log-cabin of a settler. They eagerly explained that they were "studying the customs of the country"—a phrase which thenceforward acquired a special significance.

In returning to Sudbury our train was stopped to allow Mr. Barlow to point out an intrusive contact of the Laurentian granite upon the brecciated edge of the diorite (Huronian ?), which appears to be the normal relation of the two rocks in this region. This makes it somewhat difficult to understand how the metalliferous ore has been concentrated at the original margin of the basic mass.

In the evening we were banqueted by the citizens, and after many mutually complimentary speeches retired to the "Chaudière" with the consciousness of a well-spent day.

The morning of the 29th found us traversing a sparsely inhabited region of lakes and forests to the north-east of Lake Superior. The rocks were for the greater part of Laurentian type, a matted complex of igneous intrusions mostly of granitic character, but presenting now and again a more basic "Huronian" aspect. The marks of glaciation were everywhere visible, on a scale quite inconceivable to the British glacialist—in fact, one might say that this whole day's journey was across a huge glaciated surface.

And here it may be remarked, as illustrating the immense scale of the glacial phenomena of North America, that throughout the whole of our journey of 3000 miles we were never at any one point outside the limits of the glacial deposits, and that in one shape or another the evidences of former glaciation were always visible from our car windows. Moreover, we might have gone eastward from Montreal for an additional 750 miles, to the shores of the open Atlantic, with still the same glacial surroundings!

In the early afternoon at Heron Bay, Lake Superior lay below us, and until nightfall our course ran through the bold and picturesque scenery of its cliffy margin. Old beach-terraces lying high above the present lake were pointed out to us in many places, these being the margins of different stages of the ancient glacier-dammed lake of vast extent to which the names Warren, Nipissing, &c., have been applied.

Towards evening there came a change in the profile of the land, striking alike to the geologists and the geographers, the familiar low hummocky outlines of the Archæan giving place to the bolder features of broad tabular rock-masses rising high above the lake with cliff-like sides, the bright red tints of which were strongly accentuated by the setting sun. These masses are composed of Lower Cambrian rocks (Animikie and Keweenawan), chiefly red sandstones and shales with some thin limestones, preserved under a capping of columnar diabase, which rest with the most pronounced unconformability, cake-like, upon the irregular Archæan floor, like the Torridon Sandstone on the gneiss in the North-west Highlands.

As if the elements themselves were imbued with the spirit of Canadian hospitality, not only was the weather almost throughout our tour everything one could desire, but also on this particular evening there came a fine display of aurora borealis to charm us when darkness had hidden the land.

The following day, August 30, we arrived early at Rat Portage, the chief mining centre of Western Ontario, where we found Mr. McInnes, of the Canadian Survey, just in from his camp to meet us. Here again we were received by the principal citizens, and led at once to the wharf on the beautiful Lake of the Woods, where a special steamboat had been chartered for us. The extremely interesting Archæan geology of this region has been made known to European geologists by the classic Canadian Survey Memoir of Prof. A. C. Lawson, and we rejoiced in the opportunity to examine some of the sections described by him. Our first object was to visit the highly successful Sultana gold mine on an eastern arm of the lake. On the way thither we stopped to land at one of the Indian Reservations, where a curious native burial-ground had attracted our attention; and the pathetic mementos which decorated a child's grave excited our somewhat too obtrusive interest. Later in the day we were enabled to visit a second camp, and see something of its living inhabitants.

At the Sultana Mine, where a mill of ten stamps is already at work and a number of additional stamps are being erected, we were shown the process of treating the ore, which is largely free-milling, only 20 per cent. of the gold being left in the concentrates for recovery by the chlorination process. The metal occurs in a quartz vein, at one place admirably exposed at the surface, which traverses the country-rock near the contact of granite, said to be Laurentian, with Huronian diabase. Throughout the Dominion it appears to be in similar positions around the contact of intrusive masses that the chief metalliferous deposits are found.

Led by Prof. Coleman, to whom this whole region is familiar, and by Mr. McInnes, we next ascended the hill to the east of the mine, and further examined the junction of the so-called Laurentian granite with the Huronian rocks, and noted the intrusive character of the former. Then rejoining our steamer we went westward to some islands in the lake, on which the agglomeratic and apparently volcanic character of the Huronian rocks was well displayed.

The waters of the lake were thick with a minute green floating organism, probably an alga. It is said that there are 13,000 islands in this lake alone; which may be an over-estimate, but they are certainly very numerous. We were told that they were to be bought at all prices, from five dollars upwards, so that the possession of a private island in this part of the world need not be an expensive luxury. And it might, perchance, hold a gold-mine!

Spending the night at Rat Portage the geologists were early astir next morning, and found time for further investigation of this interesting locality. Under Prof. Coleman's guidance we studied the contact of Laurentian and Huronian at several points to the westward of the town, near where the waters of the lake pour through three distinct outlets to form the Winnipeg River. It can scarcely be said that our investigations enabled us to grasp the complex relationship of these great rock-groups, though in some of the sections the gneissic Laurentian seemed clearly to be intrusive upon the Huronian. But the general impression to be gathered from all we saw of these rocks was that the term Huronian might include very different rocks in different places, and that still more was this the case with the term Laurentian. Until the Post-Archæan rocks are reached no strict divisional lines seem possible. Upon such difficult problems as these of the oldest rocks, however, the casual observer of a few isolated sections has really no right to own an opinion.

The enormous water-power which the Lake of the Woods contains, has to a slight extent already been utilised at one or the other outlet, in the production of an electric supply for the city, and for driving extensive flour-mills at Keewatin. But a fine dam is now nearly finished by which the whole outflow will be made available for industrial purposes, and it has even been proposed to convey the power to Winnipeg over 100 miles distant. The navigation of the lake between Rat Portage and Keewatin had lately been much impeded by a floating island of vegetation, but this, as we saw, had been surrounded with a boom of logs, and fixed to the shore.

Boarding the train again at Keewatin, our course lay for a few hours longer through typical Archæan country; but gradually the old rocks sank beneath the drift-plain, and before reaching Winnipeg in the afternoon we had passed once more on to a hidden platform of the Older Palæozoics, and had reached the edge of the great prairies. We were now within the basin of the glacial Lake Agassiz. This extinct lake is believed by its explorer, Mr. Warren Upham, to have extended eastward well beyond the Lake of the Woods, and westward to the "second prairie steppe" of Dr. Dawson, a breadth of about 250 miles, while the length from its termination southward in Minnesota to its northern shore against the ice-sheet north of the present Lake Winnipeg may have been nearly 700 miles; its area has been given as about 110,000 square miles, or greater than the total of the six existing great lakes, Superior, Michigan, Huron, Erie, Ontario and Winnipeg! It is to its finer sediments that the wonderfully productive character of the soil of the Manitoba prairies is largely due.

At Winnipeg, the "half-way house" of the continent, the west-bound trains stop for an hour and a half to refit. With special tram-cars at our service, we were thus able to see something of this substantial city with its many handsome buildings. The old Hudson Bay post, Fort Garry, standing in their midst, reminded us how marvellously rapid has been the growth of this western capital.

On the evening of August 31, with Winnipeg behind us, the crossing of the plains had fairly commenced. Some writer—it must surely be Lawrence Sterne—has pointed out the great value of a plain to the discursive recorder of travels. One could not do better than follow this preceptor by setting down here some general reflections which might otherwise find no place for themselves.

First, we have to regret how few in number were the British geologists to avail themselves of this magnificent opportunity for study. It is often urged against us, and not without reason, that we are too insular in our ideas and too apt to ignore the work done beyond our borders. Certainly the geologist who confines his attention solely to the neat details of British stratigraphy can scarcely hope to realise the true proportions of the problems with which the earth-student must deal. Explanations of phenomena which seem quite applicable on the small scale, often reveal their essential inadequacy under wider conditions of application. And for a corrective study of broad conditions this transcontinental journey must assuredly be unrivalled.

The railway goes more or less at right angles to the strike of the continent, and traverses therefore all the main rock-masses of which the land is built, and all the great structural features by which it is diversified. Hence the final impression which the geologist receives is that of some vast diagrammatic section of a continent. Even the scant time spent in making the traverse was, on this occasion, compensated for by the presence of the men who knew all that is yet known of the route, and who were always ready to impart what they knew.

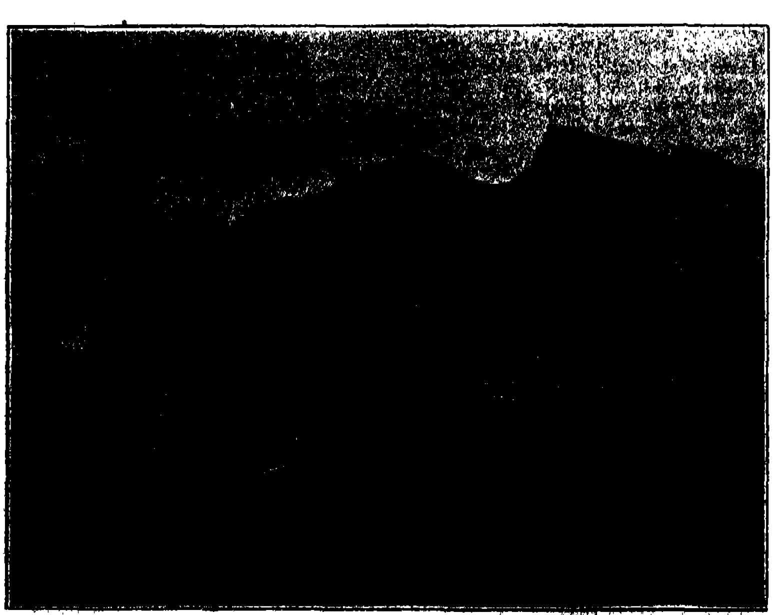
Next, although in the abstract patriotism is out of place in science, let us record the sense of gratification felt by the British members of the party, that across the breadth of this wide and prosperous Dominion we were among brothers. One could scarcely make a journey of this kind without becoming a little more Imperialist than before.

Then let us set down our admiration for the work of the

Canadian Geological Survey. Considering the means at its command, and the positively inconvenient extent of its territory, it is marvellous how much has already been accomplished, and how clearly the general structure of the country has been brought out. It was pleasant to observe, too, how well its work was appreciated among the people for whom it was primarily intended, and how in the mining districts the geological maps we carried were quite familiar to the prospectors and mining people generally, who were usually themselves furnished with copies.

And now for the Plains! They were a knotty problem for our geo-morphologists, not easily to be solved by "base-levelling" or other familiar methods, and we crossed them without properly understanding them. Considering their elevation, it is clear that they should not remain so flat!

But, taking them as we found them, we passed during the night from the first or Red River Plain to the second steppe, where there are some undulations, and before noon had crossed this also, and had reached that remarkable feature the long ridge-like Missouri Côteau, which is largely made up of glacial detritus, and is probably morainal in origin. We then reached the third steppe, which has an elevation of a little over 2000 feet above sea-level at its eastern edge, but rises gradually to over 4000 feet at the foot of the Rocky Mountains. These plains are all underlain by Laramie and Cretaceous rocks lying flat and undisturbed, containing seams of lignite, and in places yielding natural gas. There were few sections, however, either natural or artificial, excepting in the superficial drift deposits. In these drifts boulders of Laurentian rock are very numerous, many hundreds of miles from their source. The third steppe is almost entirely a cattle-ranching country, with a dry climate, as is indicated by the numerous salt lakes visible from the railway. In crossing it, the Cypress Hills, an outlier of Miocene rocks, broke the horizon to the southward, and the surface generally became more diversified than in the lower steppes.



[*From a photograph by Prof. H. E. Armstrong.*

FIG. 1.—The western or dip-slope of Mount Rundle (9635 feet); a faulted and tilted mountain-block, chiefly of Devono-Carboniferous Limestones. From Banff Hot Springs.

At Medicine Hat, in the evening, we crossed the South Saskatchewan, and under ordinary circumstances should have entered the Rocky Mountains during the night. But our director determined that we must make the approach by daylight, and gave orders that our car should be detached in the night at Calgary, where at daybreak the long range of mountain peaks was just in view. A special engine had been conjured from somewhere, and stood ready to take us forward to Banff. By this arrangement, what was for the geologist the most impressive part of the route was seen to full advantage.

As we approached the mountains we saw how the Laramie and Cretaceous rocks gradually lost their horizontality, becoming more and more tilted and crumpled as the foot-hills were traversed, until—at the entrance to the mountains—the disturbances suddenly culminated in a magnificent overthrust, as clearly visible on the bare mountain-wall as in a text-book diagram. By this thrust the Cambrian, Devonian, and Devono-Carboniferous limestones have been driven eastward over the broken Cretaceous strata for a horizontal distance estimated by Mr R. G. McConnell at seven miles, with a vertical displacement of 15,000 feet.

We stopped just long enough at Kananaskis to gain a clear impression of this grand section, and were then taken forward into the mountains.

From this point onward the line afforded a constant succession of studies for the geologist which could not fail to arouse his enthusiasm. The boldly-bedded character of the strata, with the planes often picked out by new snow, the steepness of the slopes, and the absence of vegetation, combined to bring out with the utmost distinctness details of structure which ordinarily can be discovered only after infinite labour and research. Infold and overfold, syncline and anticline, thrust-plane and fault were alike visible. Under such conditions the study of mountain-structure acquired a fresh significance, and even those of us who before had paid no attention to the subject now pursued it with zest.

The general character of this region is summed up as follows in the admirable report of Mr. McConnell[1]:—"This portion of the Rocky Mountains . . . is characterised in its eastern part by a series of great fractures and thrust faults, in the centre by broad sweeping folds, and in the west by folding and crumpling, accompanied by the development of cleavage-planes and a limited amount of metamorphism. Among its other more important features may also be noted the absence of recognisable unconformities, the absence of any of the older crystalline schists, the relatively smaller amount of disturbance in the central parts of the range than towards the edges, the want of similarity in the sequence of the formations east and west of the axis, and the marked preponderance of calcareous beds between the Middle Cambrian and the Cretaceous."

Our course lay up the Bow Valley, which is here carved out of a trough of Cretaceous rocks, wedged in among and apparently overlain by Cambrian strata. In this trough coal is mined, and although on the Plains the coal of Cretaceous age is lignite of poor character, the quality improves as the mountains are approached, until in this district both bituminous coal and anthracite are obtained.

Not only in geological interest but also in the beauty of its mountain scenery the Canadian Pacific is undoubtedly far superior to any other line crossing the North American continent. We were here within the limits of Canada's Rocky Mountain National Park, and the views we now obtained delighted us. Arriving at the well-known tourist centre, Banff, about noon, and establishing ourselves at the large new C.P.R. Hotel, where we found Prof. John Macoun of the Canadian Survey awaiting us, we set about to make the best of our time. A ridge, known as Sulphur Mountain, rising 3000 or 4000 feet above the valley to the west of the hotel, proved attractive to the more energetic of our party, and although Prof. Macoun had already made the ascent earlier in the day, he expressed his readiness to start again, and undertook the leadership of the group. For the others, who were content to view the many points of interest in the beautiful valley, carriages were provided.

From the grand outlook on the crest of Sulphur Mountain the chief features of the region were readily grasped. The Bow River far below us broke across the range, while on either hand were deep longitudinal valleys running between tilted orographic blocks of Palæozoic limestones, out of which a succession of mountainous ridges had been carved, all with precipitous faces to the east, and long dip-slopes to the west. Near the summit, about 8000 feet above sea-level, there were distinct traces of glaciation, apparently transverse to the ridge.

---

[1] Canadian Survey Reports for 1886, vol. ii. Report D, p. 40.

A hurried descent put us into fit state to appreciate the luxury of a bath from one of the hot sulphur springs, already celebrated for their restorative properties, which well up along a line of fault at the foot of the mountains. Then after a reunion at the hotel we retired once more to the "Chaudière," which had begun to assume quite a home-like aspect.

Early on the following morning, September 3, the west-bound train took us again in tow, our course for some time following up the Bow River amid scenery of increasing splendour, with glaciers showing here and there in the mountains ahead. Then, turning westward up a small tributary, the train entered the Kicking Horse Pass; and soon a painted signboard announced the Continental Divide; and we breakfasted at Field Station on the Pacific slope, with the shapely Mount Stephen just above us. From this point onward the geological structure became more complex, the foldings more acute, and the outline of the mountain peaks less and less dependent upon the bedding, and in running down the beautiful valley of the Wapta or Kicking Horse to the Upper Columbia depression we passed into the region of complication and alteration which forms the core of the mountain ranges. Thenceforward to the Pacific coast the task of the travelling geologist is difficult, and but for the work which has already been published on the Selkirks and Coast Ranges, and the presence among us of the man who had done it, we should have been at a loss to understand what we saw.

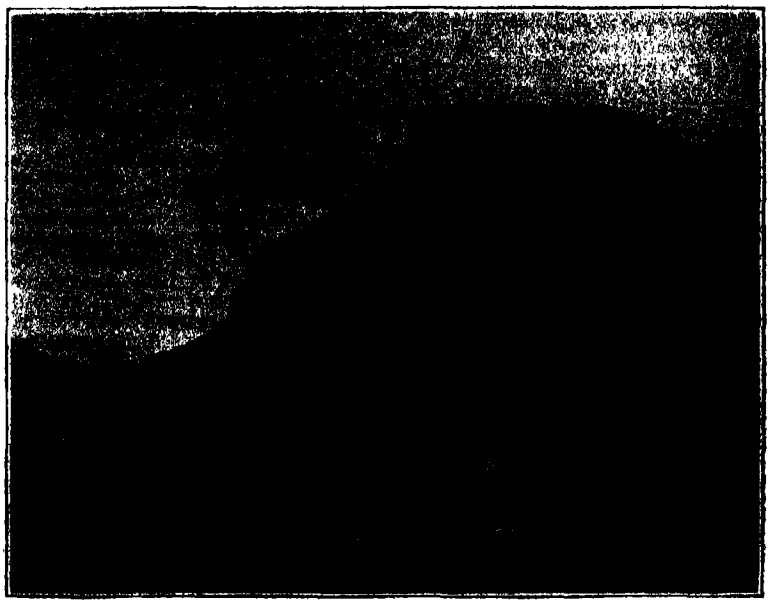
The Columbia River was reached at Golden, and was followed thence northwestward to Beaver Mouth. The great terraces of stratified material which line its valley up to high levels attracted attention both here and at Revelstoke, where the railway again crosses the river below its great north bend. Leaving the Columbia, our track turned south-westward, up Beaver Creek and Bear Creek, to make its difficult traverse of Selkirk Range. The Palæozoic rocks had now undergone a great change of character, and instead of the flaggy limestones of the Eastern Rockies, we found ourselves among unfossiliferous argillite schists and quartzites, everywhere highly disturbed and sheared. The denser timber and the many long snow-sheds lent additional obscurity to our geological impressions.

Around Rogers' Pass, 4300 feet above sea-level, lies the finest mountain scenery of the whole route, but on this day the highest tops were hidden in clouds. A short run from the summit brought us, at 2 p.m. or 14 o'clock railway time, to our next halting-place, the C.P.R. Hotel at Glacier.

At this place our first objective was, of course, the grand Illicilliwaet Glacier, the snout of which lies two miles back in the forest. Around the glacier a busy afternoon was spent—one of our party, expert in such work, fixing points for measuring its future recession; others scaling the lateral moraines of blocks of sheared quartzite in which blue quartz grains were conspicuous; others attacking the glacier itself, and studying the fine display of structures which the body of the ice reveals. But the time was, of course, too short for more than a mere skirmish around its lowermost portion, and the great icefields above remained unseen.

It had been proposed on the following morning to climb one of the ridges overlooking these icefields; but here for the first and only time the weather failed us, and though after breakfast Prof. Coleman, who made light of all obstacles, led the way towards the Asulkan, another of the many glaciers of this region, he found but few followers to face the discomfort of the saturated forest.

Some curious feats in engineering have been performed in carrying the railway down the western slope of the Selkirks, but none are more remarkable than the great "loops" by which the descent is made from Glacier into the cañon of the Illicilliwaet. After leaving this place we had all around us the heavy timber of the Pacific region, making, where unburnt, a fine foreground to the peaks and glaciers behind. But the wholesale devastation which has been wrought by forest fires throughout this region is distressing to any eyes but those of the Western man who has come to regard timber as the chief hindrance to the rapid development of his country.



[*From a photograph by Prof. H. E. Armstrong.*

FIG. 2.—The eastern face of Mount Rundle, Banff.

At Albert Cañon the train stopped long enough to allow our photographers to spoil their plates in attempting views of a sombre river-gorge. At this point the dark schists with a band of crystalline limestone (part of the "Nisconlith Series" of Dawson) are believed to lie very near the base of the sedimentary rocks of the Selkirks. At any rate, a short distance further west we entered upon the region of gneiss, mica-schist and granite, which the Canadian geologists recognise as a portion of the Archæan nucleus or axis. Out of such rocks the western part of the Selkirks and much of the Gold Range have been carved. We found opportunities to examine them, during the return journey, at a few points around Revelstoke and Arrowhead, and from their intricate structures one might judge that several different stages of movement and several distinct periods of eruption were represented. Unlike the conditions in Eastern Canada, in British Columbia westward of the Selkirks the Palæozoic and even Mesozoic rocks are so involved and altered among eruptive and intrusive masses, and so implicated with each other by the earth-forces which have built up the mountain-ranges, that the evidence for age is rarely at hand, and one would need to be thoroughly well acquainted with the country to pronounce upon any part of it. But one could see that these schists and gneisses form the Central Complex of the ranges; and they seem of high antiquity. In travelling from east to west across the mountains we had seen the effects of crustal forces of gradually increasing intensity, acting usually from west to east. We were now upon the focus of these forces, where their intensity had obscured the evidence.

At Revelstoke, the same evening, the Columbia was crossed for the second time, the great river flowing south-easterly here, instead of north-westerly as where we had crossed it on the previous day, on nearly the same latitude, but about 150 miles nearer its source. The valley systems of this part of the continent are peculiarly interesting for the physiographer, and present some curious problems which are yet unsolved. In this instance the Columbia and its great tributary, the Kootenay, have their sources close together in the same great valley: the one flows north, and then swings round sharply southward; the other flows south, and swings northward to their union, the Selkirks and associated mountain ranges being thus completely encircled. Among our party were those who have struggled bravely with such problems, and to their investigations we shall look for further enlightenment.

From Revelstoke the C.P.R. Company has a line of communication by rail and steamboat into the celebrated West Kootenay mining district, by way of that beautiful expansion of the Columbia River known as the Arrow Lakes. Through the liberality of the British Columbian Government, side-excursions were organised into this region, and on our return from Vancouver the majority of our party took advantage of the opportunity to visit the brand-new mining town of Rossland, around which are grouped the chief mines of the district. Here, as everywhere else in the province, every facility was afforded us to see all that was best worth seeing. We visited such well-known mines as the Le Roi, War Eagle, Centre Star, &c., where large deposits of auriferous chalcopyrite and pyrrhotite occur, chiefly in veins near the margin of a mass of gabbro intrusive into Palæozoic rocks. The large smelter at Trail, on the Columbia Railway, a few miles distant, was also visited; and those of us who could spare the time went afterwards into the Slocan country, where the richest mines of silver-lead occur. Space forbids a detailed account of these and other branch excursions in the Province; but if it was intended that we should come away impressed with the mineral wealth of the region, that end was assuredly attained.

It was but a twenty hours' journey from Revelstoke to the coast at Vancouver. After rising out of the Columbia depression the railway finds an easy passage through the Gold Range by the Eagle Pass, apparently a valley of erosion now abandoned; though the suggestion had been made that it was providentially supplied to compensate the engineers for their difficulties in the Selkirks and the Rockies.

A chain of small lakes fills the summit of this Pass, to the westward of which lie many fine moraines. In Eagle River, on its western slope, we were fortunate in witnessing a good example of a salmon run, shoals of great fish crowding the shallows of the stream in every part, and lying dead on every bar.

Shuswap and Kamloops Lakes, and the dry interior plateau of British Columbia with its Tertiary volcanic rocks, were passed in the night, and at daybreak of September 5 we were running down the picturesque cañon of the Thompson River, near its junction with the Fraser. In the Fraser Valley itself there is in this neighbourhood a sharp infold of Cretaceous strata; but lower down we saw only ancient-looking slates, supposed to be Cambrian, along with masses of igneous rocks, both of acid and basic types. Near North Bend, where we breakfasted, a dredger was at work raising the auriferous gravel from the river bed. Below this the valley narrows, and the Fraser races southward for miles through a magnificent cañon, down which the railway also passes. Then, at Yale, the river bursts out of the mountains and swings round westward into a broader and apparently much older valley, which it follows from Hope to the Pacific. Following the river, our track went now amid the dense forest of gigantic trees with which the valley is filled, cleared spaces being as yet quite scanty. Of the Laramie or newer rocks which underlie the Fraser delta, we saw nothing, as on the low ground there is everywhere drift and alluvium. Reaching Pacific tide-water at the head of Burrard's Inlet about noon, we drew up at Vancouver half an hour later.

Our long delightful railway journey was completed, and with it our transverse section of the continent. Starting within the Appalachian rim, we had seen, to the east of the prairies, the old Archæan floor on which the Palæozoic strata rested almost undisturbed; then the prairies themselves, with their vast expanses of horizontal, unfaulted Mesozoic rocks; then the foot-hills, with the same rocks thrown into wavelike swells; then the outer mountains, with dislocated and overthrust masses of various ages, driven eastward from the centre of disturbance; then the inner ranges, with crumpled and altered strata whose age was no longer determinable, and with the central core of metamorphic and plutonic rocks; and then again, to the westward, infolded and crumpled sediments with many igneous interruptions.

All this had, of course, been described for us already by the Canadian geologists in their admirable official and other publications. But what literature could hope to convey an adequate impression of such a region to one unacquainted with it?

At Vancouver most of us took boat at once across the Straits of Georgia, a few on whom time pressed crossing to Nanaimo, and the majority going first to Victoria, whence a special excursion was afterwards made to Nanaimo. It was a glorious afternoon for the passage—the mountains around Howe's Sound half hidden under storm-clouds and half revealed, and a foreground of high gloomy shores, with the deep recesses of the fjords within gleaming with mysterious light.

On Vancouver Island the heartiest hospitality again awaited us, but of our doings there is small space left to tell. In Victoria we found many of our friends of the two earlier parties, and we of the "Chaudière" held a banquet to do honour to our leaders Dr. Dawson and Prof. Coleman. On Monday we were taken in carriages to the points of chief interest in the vicinity of the city; on Tuesday there was a special train to take us to Nanaimo, where coal of excellent quality is extensively mined from rocks of Cretaceous age; and on Wednesday a number of those who intended to visit the Kootenay started for the mainland. Safe to say that we all left the city of Victoria with reluctance, as most do who visit it.

And now the unity of our party was lost, and its fortunes need be no further followed. For all of us this had been a memorable journey, and we started homeward with a lively sense of gratitude to the Local Committee at Toronto, to the Provincial Governments of Ontario and British Columbia, to the Canadian Pacific Railway Company, and, above all, to our leaders Dr. G. M. Dawson and Prof. A. P. Coleman, by whose exertions the complete success of the excursion was secured.

PROFESSOR VIRCHOW'S JUBILEE.

FIFTY years ago Prof. Virchow delivered his first lecture as a university teacher, and preparations for celebrating the event of the jubilee at Berlin last week had been made, but unfortunately had to be abandoned in consequence of a sudden attack of illness which befell Prof. Virchow whilst lecturing two days before the anniversary. Naturally some alarm was felt, but the attack was not serious and passed off quickly. However, at Virchow's request, the festive arrangements were countermanded, and the day was only marked officially by a congratulatory deputation from the University. According to the Berlin correspondent of the *British Medical Journal* the deputation consisted of the deans of the four Faculties, and nearly all the medical professors. Prof. Schmoller, the University Rector, spoke first, and in a warm and able address praised Virchow as the benefactor of millions, and as the great instructor whose methods had gradually permeated almost all schools of thought. Then followed Prof. Heubner, the Dean of the Medical Faculty. He spoke of Virchow's strong personality, and described the commanding impression caused by his teachings which had revolutionised medical thought. It was true that what might be called Virchow's greatest lifework was the introduction of "methodology" into medicine, but this alone did not explain his immense influence. He had pre-eminently the genius of research, and had traded with his talent as a faithful steward. At an age when others had not finished their studies he had attacked scientific problems with his bold and strong intellect, had gone on from problem to problem, until after ten years his work was crowned by the completion and publication of his "Cellular Pathology." Since then he had become the *præceptor mundi* in medicine. Prof. Virchow, in reply, modestly disclaimed what he called excessive honours. He said he felt like a plant from which the withered leaves had been removed to give it a better appearance. He could not deny that his work had always been full of zeal, and supported by the endeavours to keep in view universal principles; and it was true, also, that a certain soberness of judgment had helped him over great difficulties. If he had succeeded earlier than others in forming a school, he owed this to his recognition of the fact that it was impossible to do everything oneself, and to his success in creating a sort of phalanx for his ideas, which had been of sufficient force to overcome resistance, and to prepare a broad basis for later developments. And thus, he was happy to say, he now felt himself no longer indispensable as representing his school, since there were a sufficient number of men sharing his views. He hoped that his little attack of the day before would have no further consequences, and that he had yet some time for work before him; still he could not hide from himself that it was now time to make a stop, to a certain extent; and therefore he was doubly glad that he had lately succeeded in convincing the Government that somewhere in Germany there must be a place where every student could at all times find instruction on questions of pathology and medicine, that he had been instrumental in securing the rebuilding of the pathological museum.

THE TEMPERATURES OF REPTILES, MONOTREMES AND MARSUPIALS.[1]

THERE has for many years past been a tendency to diminish or ignore the distinction between the cold-blooded and the warm-blooded types of animal life. Yet the difference is one that is not only real, but in some respects radical. In very few, however, of nature's classes is there found a line of sharp demarcation, and the chief purpose of this paper is to point out that, though the distinction between the two types is real, there lies between these two types a line of steady gradation.

Although the invertebrates have the capacity of producing heat, they are themselves cold-blooded. With the exception of the insects, they very rarely rise more than a fraction of a degree above the temperature of the media in which they happen to be. According to observations of Prof. Valentin, polypi, medusæ, echinoderms, molluscs, crustaceans and cephalopods are able to raise themselves about a fifth of a degree, sometimes as much as three-fifths of a degree, above their environment.[2]

Among insects the power of heat-production is very much greater. Though essentially cold-blooded creatures, in the sense that they have no fixed standard of body-heat towards which they approximate, they are almost always warmer than their media; but if they are at rest that excess is only a degree or two. In case, however, of severe exertion, they are capable of warming themselves to a remarkable extent.

In the case of fish, amphibia and reptiles the same is true. At rest all of them remain at the temperature of their environment, rising and falling with it, and showing no capacity, however rudimentary, of maintaining a fixed and characteristic temperature; yet all can warm themselves by exertion. The large blue-tongued lizard, which is common in the southern parts of Victoria (*Cyclodus gigas*), can warm himself as much as half a degree in ten minutes of anger. In five experiments of this sort I found that different individuals had different capacities of being irritated, but the average was a trifle under half a degree for ten minutes of exasperation.

By activity, and consequent heat-production, all fish, amphibia and reptiles seem able to keep themselves a little warmer than the air or water in which they dwell. Dutroche tells us (*Ann. des Sciences Nat.*, xiii. p. 20) that the newt can keep itself from 2° to 5½° above the temperature of its medium, the turtle 1⅓° to 3⅞°, and the common green lizard of France (*Lacerta viridis*) from 4° to 7°. Max Fürbinger asserts that species of blind-worm rise as much as 8° above the temperature of the air. Fish at rest appear to take almost absolutely the temperature of the water wherein they live, but after a struggle, or any other form of energy, they may warm themselves two or three degrees.

This, however, has no real affinity with a warm-blooded habit. And yet these creatures approach in a remote way the warm-blooded condition by sometimes developing a capacity for heat-production in the action of their viscera. Dumeril has shown that snakes by mere digestion can warm themselves from 2° to 4°, the maximum temperature occurring about twenty-four hours after a meal.

Thus it constantly happens that these animals, though essentially cold-blooded, may be observed at temperatures somewhat above that of their environment. But in general that excess is not great, and it leaves the distinction between the warm-blooded and the cold-blooded type quite unaffected.

The true criterion of the difference is of course the concomitance of the temperature of the animal and its medium. An animal of the warm-blooded type may vary a trifle in its general body temperature when the climate alters, but it maintains an almost constant degree of heat. The reptile, though it may maintain itself a few degrees above the surrounding temperature, always varies with it, rising and falling so as to keep always the same number of degrees in excess.

To see how far this concomitancy held, I placed two specimens of the large lizard already mentioned into a small tank of water, so that only their noses were above water. I then warmed up the water at various rates of speed by means of one or more lamps. The accompanying diagram (Fig. 1) shows how closely the lizards followed the temperature of the enclosing water.

Cyclodus gigas is a very sluggish creature, and if left alone never warms himself by any exertion, yet if one takes his temperature in the early part of the day it will almost always be found to be below that of the air. After sunset it is generally higher. During two years I kept specimens of this species in a box, sometimes six or eight, sometimes only two or three. I took their temperatures morning and evening, not altogether continuously, but throughout the larger portion of that time. The average of all these observations gave for lizards 18°·1, for the air 18°·4. This is a very close approximation considering that the temperatures had the wide range that lies between 12° and 32°. The lizards appear to be a little colder than the air. This I believe to be due only to the fact that, taking temperatures before eight o'clock in the morning, the lizards were still considerably in the rear of the temperature, while between five and six o'clock in the evening, though they were above the air temperature, the excess then did not wholly balance the morning deficiency.

I am convinced that if one took the temperature of a quiet lizard every hour for a month, the average would correspond almost exactly with the average temperature of the air. The morning and evening observations which I took would give a less exact result, though from them the difference is only three-tenths of a degree.

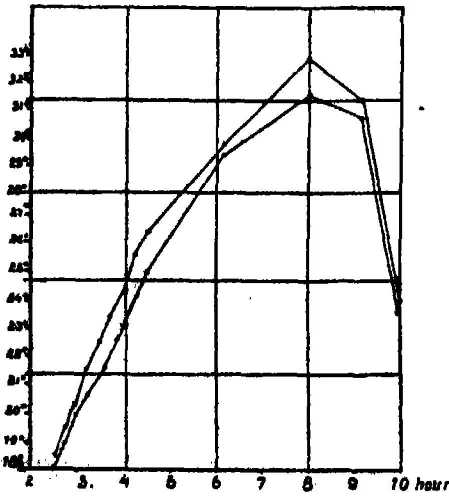


FIG. 1.—To show concomitance of temperatures of lizards and water. Upper line, temperature of water; lower line, temperature of lizards.

The steps whereby the more active and intelligent warm-blooded types have arisen from the lethargic level would form a fascinating subject for inquiry, but I purpose here only the much easier and more prosaic one of recording that such steps, however caused, do actually present themselves, and that these are in the most perfect accordance with the existing classification, which is based on anatomical considerations alone.

The monotremes are, in consideration solely of their more reptilian anatomy, placed lowest in the scale of mammals. Their low temperature would entirely justify, were justification in any way needed, the position thus assigned them next to the reptiles. The temperature of the duck-billed platypus has been determined by Baron Miklouho-Maclay to be, as the average of three observations, 24°·8 when the water in which the animals were kept averaged 22°·2 (*Journal* of Linnean Society of N.S.W., viii. p. 425, and ix. 1204.)

Now, the average of forty-five specimens of the ten higher orders of the mammalia, excluding the monotremes and marsupials, is 38°·9, as calculated from Dr. John Davy's lists (*Edin. Phil. Journal*, 1825, p. 300), while the average of a similar but shorter list supplied by Max Fürbinger is 39°. We may take this as fairly indicative of the general mammal temperature, which does not, except in constitutional disturbances, vary so much as two degrees on either side of this limit. No mammal indeed seems in good health to be warmer than 40°; scarcely any descend lower than 37°.

---

[1] By Alexander Sutherland. Abridged from the *Proceedings* of the Royal Society of Victoria, vol. ix. (New Series), 1897.

[2] All degrees in this paper are Centigrade.

The platypus, therefore, at only 24°·8 is almost a cold-blooded animal. The only other genus of monotremes, the echidna, carries us a step upwards. Baron Miklouho-Maclay's average of five observations is 28°, while the air was 20°. I have kept at different times fourteen specimens of *Echidna hystrix*, and made twenty-seven observations on the temperatures of all I happened to have at any particular time. I found the average to be 29°·4, or nearly a degree and a half above that of the Baron. But these animals show their affinity with the reptiles by a temperature so variable with the weather that we may readily expect the average of one series of experiments to differ very considerably from that of another.

An echidna one cold morning was as low as 22°; another, brought in from the forest in a sack exposed to a fierce midday heat, registered as high as 36° 6. The accompanying diagram (Fig. 2) represents the general character of the variations, the temperatures in each case being the average of from three to six individuals, which never vary from one another at the same time more than a fifth of a degree.

It will be seen that the temperatures of the echidnæ varied from 22° to 36°·6. This is an immense range for a mammal, and suggests a reptilian want of capacity for temperature regulation. Moreover, though the concomitancy between the air and the body temperatures is by no means strict, there is enough to show that the one in a large measure follows the other. It is to be remembered that while a monotreme may rise and fall with the air, yet the one change will follow the other after a definite period of time, and an hour after sunset, though the air in a box may have grown much cooler, the echidnæ in that box may have only begun to cool.

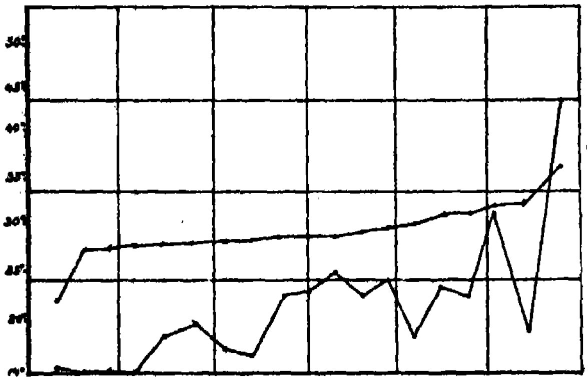

Fig. 2.—To show want of concomitance in the temperatures of Echidna and air. Upper line, Echidna; lower line, air.

The next stage in the anatomical classification brings us into the order of the marsupials, and here again we make an upward step in view of a temperature higher, but not so high as that of mammals in general; steadier, but not so steady as is usual in all the remaining orders. I have observed the temperatures of sixteen different species of marsupials, and they average 36° exactly, as the result of 126 observations. They are thus 3° below the average of other mammals.

The marsupial whose temperature, so far as I have observed, comes next above the monotremes is the wombat, which stands at 34°·1, as the average of single observations made on two specimens (*Phascolomys lasiorhinus*, 34°·3, and *P. platyrhinus*, 34°). Next seems to stand the genus Petaurus, or flying squirrel. Mr. Ernest Le Souëf was good enough to observe for me the temperatures of five specimens in the Zoological Gardens of Melbourne. The average is 35°·7.

After that comes the genus Phascolarctos, our little native bears or koalas. I have kept numerous specimens of this animal (*P. cinerus*) on his native gum trees, with nothing artificial about him save a strap and rope whereby he could be pulled down from time to time to have his temperature observed. Thus I made eighty-three observations, the average of which amounts to 36°·4. Females at the breeding time are always very decidedly above the ordinary degree of warmth. If such cases be excluded, the average is exactly 36°. But the average for males alone is only 35°·2. The range of variation may be seen in Fig. 3.

The range is not very wide, yet I have often known healthy specimens that had been for a while in the sun stand as high as 37°·9, while on a cool day or in a very shady place the same individuals would be only 35°·3, a range greater than we would find under the same circumstances in any of the higher mammals. The highest register I ever obtained for a thoroughly healthy koala was 38°·4, which is a degree and a half above the normal temperature of man; the lowest was 34°·9, or nearly two degrees below man's normal.

According to observations taken for me by Mr. Ernest Le Souëf, the Dasyures come next at an average of 36°.

Phalangers stand next in order. The average of twenty-two observations on from two to four specimens of the ring-tailed opossums (Phalangista) gave 36°·6, which is only a little below the normal human temperature. But again the range was much greater than one finds in any of the higher mammals. In cool weather, with the thermometer at 16°·8, a male would register about 35°, a female about one-tenth of a degree higher; but in warmer weather, though still in the shade, where the thermometer registered 31° to 35°, the opossums would be about 37°.

Mr. Ernest Le Souëf took for me the temperatures of three of these Australian opossums in the Melbourne Zoological Gardens. *Phalangista vulpina* gave 36°·1, *Phalangista fuliginosa* 37°·3. This corresponds with Selenka's observations of the true opossums (Didelphys), which ranged about 37°.

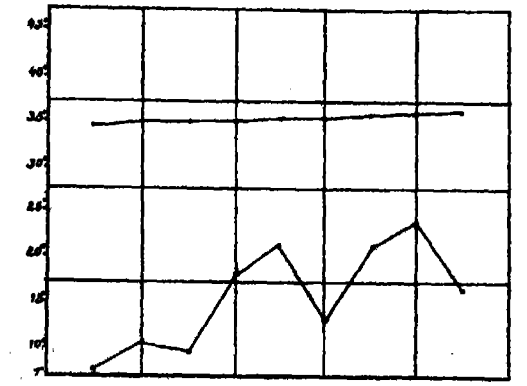

Fig. 3.—To show want of concomitance in the temperatures of Koala and air. Upper line, Koala; lower line, air.

I have made only four observations on the temperatures of the kangaroo family. They are a little under the human standard. *Macropus giganteus* gave 36°·6, *Halmaturus bennettii* gave 37°·1, *Petrogale xanthopus* 35°·9, while the tree kangaroo (*Dendrogalus grayi*) was exactly at the human standard, 37°.

From the few recorded temperatures of rodents and insectivores, I should think it most probable that they came next in order, with perhaps the Cetacea and Sirenia, judging from occasional records, as almost on the same level. All the other orders of mammalia stand uniformly much above the human temperature.

It is clear, therefore, that there are grades of temperature, and that the mammals which are classed lowest on anatomical grounds are not only of the lowest temperature, but also of the greatest range, and they are likewise, of all mammals, those which are under the strongest and most direct influence of the temperature of the environment.

Similar, though much less complete connecting links may be seen in the case of birds. The lowest of birds are the Ratitæ, or Cursores, and these appear to have the lowest temperature. Mr. Ernest Le Souëf took for me in the Melbourne Zoological Gardens observations on the temperature of the emu. These are the lowest records of bird temperatures of which I know. They averaged 39°·5, while all the birds above the Ratitæ are invariably over 40°. The temperature of thirty-six fowls, taken quietly by night from their perches, averaged 41° exactly, while that of twelve, lifted from the nests in which they were brooding, was 41°·4. Numbers of fowls caught while roaming about averaged 41°·3, but these of course were always warmed up previously by a little violent exercise. Turkeys stand about the same level; ducks are stated, on good authority, to be lower; but I have found for these birds, from a fairly large number of observations, an average of 42°·1. The temperatures of birds of the more intelligent orders is generally somewhat higher. If we exclude the birds of prey, we might say that in all orders above the anseres, grallæ and gallinæ the temperature ranges over 42°. It would be a matter of interest to secure some observations of the temperature of the apteryx, in order to determine whether the lowest of birds shows by its body warmth in some degree the same reptilian affinity which the monotremes exhibit. In that case there would be reason to believe that the rest of the Ratitæ would correspond closely to the Marsupials, being a connecting link, but much closer to the higher forms than to the lower.

In a very general way, and not forgetting numerous limitations and contradictions, it may be said that bodily activity depends on body temperatures, that creatures such as insects and reptiles are active only when warmed up from without, but become torpid with decreasing temperature. The type in which activity is generally habitual, maintains its own body temperature. This is seen in the mammals, but more still in the birds. But this warm-blooded active condition was produced by no sudden emergence; the monotremes and marsupials form a gentle gradation between the reptile and the carnivore or ungulate: while, so far as indications point, there is reason to believe that the lower birds still are reminiscent of a once existent chain of links which equally joined the cold-blooded lizards to those warmest-blooded of all creatures, the passeriformes and fringilliformes.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Dr. W. T. Brooks has been appointed Litchfield Clinical Lecturer in Medicine.

The Welsh Prize for Human Anatomy for 1897 has been awarded to Mr. A. T. Waterhouse.

W. K. Spencer, of Batley Grammar School, has been elected to a Demyship in Natural Science at Magdalen College, and A. J. Webb, of Dulwich College, to an Exhibition.

Convocation has conferred the degree of M.A., by decree, on Mr. A. A. Rambaut, the newly-appointed Radcliffe Observer.

Prof. Gotch and Dr. Buckmaster have been appointed Examiners in Physiology, and Prof. Allbutt and Dr. Ormerod in Medicine for the M.B. Examinations from 1898–1900.

Mr. N. V. Sidgwick, Ch. Ch., is President of the Junior Scientific Club for the present term. The other officers are: Treasurer, Mr. A. E. Boycott (Oriel); Editor, Mr. A. R. Wilson (Wadham); Secretaries, Mr. A. Hartridge (Exeter), and Mr. F. Nunneley (B.N.C.).

CAMBRIDGE.—Dr. Shore, of St. John's College, has been appointed Chairman of the Examiners for the Natural Sciences Tripos, and Dr. Hobson, of Christ's College, for Part II. of the Mathematical Tripos.

The Arnold Gerstenberg Studentship, for natural science students who distinguish themselves in Moral Philosophy, has been awarded to Mr. C. F. G. Masterman, of Christ's College.

By the will of Mr. Joseph Gedge, M.B., who died at Khartoum in 1870, while acting as medical officer to Sir Samuel Baker's expedition, a sum of 1000*l.* has now come to the University for the foundation of a biennial prize in Physiology. The recipient is to be a graduate of the University of not less than five or more than seven years' standing from matriculation, who sends in the best essay embodying original observations in physiology, including histology, physiological chemistry, and physiological physics. If the prize is not awarded on any occasion, the accumulated income of the fund is to be given to the Museums of Anatomy and Physiology.

At St. John's College the following awards in Natural Science have been made to students not yet in residence:—80*l.* scholarships, Williams, of Pocklington School, and Wakely, of St. Olave's School; 70*l.* scholarship, Gregory, of University College, Bristol; 50*l.* minor scholarships, Crocker, of Llandovery College, and Macalister, of Charterhouse; 50*l.* exhibition, Browning, of Dulwich College.

At Trinity College the corresponding awards are as follows:—75*l.* minor scholarship, Harrison, of Royal College of Science, London; 50*l.* minor scholarship, Hamill, of St. Paul's School; 40*l.* exhibitions, Keeling, of Bradford School, and Scott, of Rugby School; sizarship, White, of Royal College of Science, London.

THE death is announced of Dr. Arthur Scheffer, formerly professor of chemistry and medical physics in the University of Kieff.

THE Calendar for the seventeenth session (1897–98) of the University College, Nottingham, has just been published at Nottingham by Mr. J. Sands.

MR. ARTHUR HAMILTON WHITE has been appointed professor of pathology in the school of the Royal College of Surgeons, Ireland, in the place of Dr. Thomas Myles, resigned.

A LABORATORY for experimental psychology has been opened, under the direction of Dr. W. O. Krohn, in the Illinois Eastern Hospital for the Insane, at Hospital, Ill.

AT a meeting of the Court of the Victoria University, held at Owens College, Manchester, Prof. D. J. Leech was re-elected a member of the Council. It was resolved: "That the colleges of the University be invited to take such steps as may be necessary to secure the inclusion of the colleges in the list of institutions at which Royal exhibitions and national scholarships can be held."

THE Kingsley Laboratory of the Worcester Academy was dedicated on October 30. Addresses were delivered by President Eliot, of Harvard University; President Hall, of Clark University, and President Mendenhall, of the Worcester Polytechnic Institute. The building is said to be the best equipped for the study of science possessed by any secondary school.

GEHEIMER BERGRATH BRUNO KERL, professor of metallurgy at the Berlin School of Mines, has retired after more than fifty years constant professorial work at Clausthal and Berlin. He has been a voluminous contributor to the literature of metallurgy, and for thirty-eight years he was one of the editors of the *Mining and Metallurgical Journal* of Leipzig. On his retirement the German Emperor bestowed on him the Order of the Red Eagle in recognition of his great services to metallurgy.

THE following appointments abroad are noticed:—Dr. Charles W. Dabney, recently assistant secretary of agriculture, to be president of the University of Tennessee; Dr. Arthur Allin, of Ohio University, to be professor of psychology and pedagogy in the University of Colorado; Dr. Hermann Munk to be full professor of physiology in the University of Berlin; Dr. Hettner, of Leipzig, to be assistant professor of geography in the University of Tübingen, Dr. Max Busch to be assistant professor of analytical chemistry and chemical technology in the University of Erlangen; Dr. Zwaardemaker to be professor of physiology in the University of Utrecht; Dr. Frank K. Cameron, late associate professor of chemistry in the Catholic University of America at Washington, to be research assistant in physical chemistry in Cornell University; Dr. O V. Darbishire to be lecturer (privat-docent) in botany at the Prussian University of Kiel; Dr. A. R. Hill has been appointed to succeed Prof. Wolfe at the University of Nebraska. The chair vacated by Prof. Hill at the Osh-Kosh Normal School has been filled by the election of Dr. F. D. Sherman.

THE Report of the Council of the London Society for the Extension of University Teaching, for the session 1896–97, has reached us, and is of an encouraging nature. The number of courses for the session under review was 160, as compared with 148 for 1895–96, and the number of students for the two periods, in the order named, was 14,150 and 13,238. The slight falling off in the number of certificates awarded (1807 in 1896–97, as against 1906 in 1895–96) is explained by the alterations made in the Regulations of the Education Department with regard to the Queen's Scholarship Examination. Candidates are now only allowed to take the University Extension examination as an alternative to the Queen's Scholarship examination in the same subject, whereas formerly the possession of a sessional certificate secured a block of sixty marks in addition to those obtained in the ordinary examination. The Council anticipated that this alteration would make a much greater difference in the number of pupil-teachers working for sessional certificates than has been the case. They have been much gratified by the enthusiasm shown by the heads of pupil-teachers' centres with regard to University Extension teaching, in their efforts to keep in connection with the Society under the altered conditions. Pioneer courses of lectures, the expenses of which have been borne by the Technical Education Board of the London County Council, have been given at Bethnal Green, Poplar, Queen's Park, St. Pancras, Shoreditch (two courses), Walworth (two courses), and Wandsworth. These courses were attended by about 3500 people, almost exclusively of the artisan class. The average attendance at each lecture was 387. In two of the districts regular extension centres have been formed as the result of the lectures. In connection with these courses the illustrations of scientific principles are largely drawn from the industrial developments of the district with which the working men are particularly acquainted. Thus the course on "Electric Power and Lighting," given by Dr. Laurie at the Town Hall, Shoreditch, in the Lent Term, was fully illustrated by views of the Shoreditch electric installation, and created an intense interest in the subject among the working men, who attended in great numbers. A large proportion of the audience remained for class instruction after the lectures; many did regular weekly paper work, and forty obtained the certificates of the Society as the result of the terminal examination.

SCIENTIFIC SERIALS.

American Journal of Science, November. — Geology of Southern Patagonia, by J. B. Hatcher. This is an account of the results of an expedition into Argentine Patagonia made for the purpose of collecting vertebrate fossils for Princeton University. The oldest sedimentary deposits seen were a series of black, very hard, but much fractured slates, with Ammonites fairly abundant, but not sufficiently well-preserved to admit of identification. These beds are referred to the Jurassic, chiefly on account of their lithological characters and the great thickness of the overlying rocks, which, to judge from Dinosaurian remains, can hardly be more recent than the Cretaceous. The beds of basalt observed by Darwin on ascending the Santa Cruz River are not due to a flow from the distant Cordilleras, but to small local craters.—The former extension of the Appalachians across Mississippi, Louisiana, and Texas, by J. C. Branner. Gives additional facts in support of his thesis that the old Appalachian land area crossed what is now the lower Mississippi valley. The coal-measures drainage of the Illinois-Indiana-Kentucky basin flowed westward through the Arkansas valley into a carboniferous Mediterranean sea. The drainage of the coal-measures region south of the Ouachita anticline flowed westward and entered this sea north of the Texas pre-Cambrian area. The drainage of both the Arkansas and Texas carboniferous areas was reversed about the end of Jurassic times, when orographic movements over south-east Arkansas, eastern Texas, Louisiana, and Mississippi submerged the former extension of the Appalachian watershed, and admitted the early Cretaceous sea across the Palæozoic land as far north as southern Illinois.—The combustion of organic substances in the wet way, by I. K. Phelps. Carbon dioxide may be estimated iodometrically with a fair degree of accuracy. It may, therefore, be applied to the determination of organic carbon oxidised by liquid reagents, such as potassium permanganate or chromic acid. The former was used for oxidising oxalates, formates, and tartar emetic; the latter for these and cane-sugar and paper. The method is very successful in the case of the less volatile organic compounds.—Some features of the pre-glacial drainage in Michigan. In all the glaciated area of North America no region is so extensively and deeply covered with drift as the lower peninsula of Michigan. The author works out the probable features by analogy with unglaciated areas, and constructs a map showing the probable carboniferous river system.

Wiedemann's Annalen der Physik und Chemie, No. 10.—Observation of Zeemann's phenomenon, by W. König. The author observes the dark sodium lines produced by an arc light traversing a sodium flame. The broadening in a magnetic field is detected by a differential method. A quarter-wave plate and a doubly-refracting prism are used to obtain two images of the slit joining across a narrow line. The extinction of the circularly-polarised right-hand edge in one image, and the left-hand edge in the other, gives the appearance of a lateral displacement which is reversed by turning the prism. A total displacement of 1/28th of the distance between the D lines is thus obtained in a field of 7300 units.—On the rate of depolarisation of electrodes and on dielectric constants at low temperatures, by R. Abegg. This is a criticism of Dewar and Fleming's alleged enormous capacities of certain dielectrics at very low temperatures. The author maintains that these are only apparent, and are really due to the very slow depolarisation of electrodes in great cold, so that the current obtained from the condenser is a polarisation current instead of being a dielectric current.—On the depolarisation of mercury and platinum electrodes, by K. R. Klein. Large and small electrodes dipped into various acid and salt solutions, and the course of their polarisation by a known E.M.F. and their subsequent depolarisation, was investigated by means of a capillary electrometer of negligible capacity. It was found that the rate of depolarisation was nearly independent of the area of the electrode and of the nature of the solution, but was much accelerated by heat and by the presence of a salt composed of the electrode metal as a base, and the acid of the electrolyte.—An electro-chemical method of converting alternating into direct currents, by L. Graetz. Cells in which aluminium forms the anode do not transmit currents having a voltage below 22. Alternating currents may therefore be converted into intermittent currents by means of a battery of such aluminium cells. The author describes an arrangement for obtaining a direct pulsating current by the same means The apparatus forms a convenient "rectifier."—Researches on lampblack, by J. Stark. The specific gravity of solid lampblack is forty-three times that of lampblack as deposited. One cc. contains 1,270,000 million particles of lamp black. The author obtained polished surfaces of lampblack, and proved that as regards elliptic polarisation they occupy a place intermediate between transparent substances and metals.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, November 12.—Mr. G. Johnstone Stoney, Vice-President, in the chair.—Mr. J. Rose-Innes read a paper on the isothermals of ether. The well-known generalisations of Boyle and Gay-Lussac with regard to the pressure, volume, and temperature relations of gases, were examined by Ramsay and Young, who deduced the law $p = bt - a$, *i.e.* that pressure is a linear function of temperature, at constant volume, where b and a are functions of volume only. It yet remains to discover the form of these two functions b and a. The author finds b and a for a large number of volumes, and from them devises an empirical formula. As a preliminary step he examines whether any single algebraical expression can represent the case, so as to determine the probability of discontinuity. For this purpose a graphic method is applied. By plotting $(av^2)^{-1}$, against $v^{-\frac{1}{2}}$, a curve is obtained of "cusp" shape. The point of the cusp occurs very near critical volume, it suggests discontinuity in the slope of $(av^2)^{-1}$. The author concludes that there is extremely rapid change of behaviour of the gas at this point. Again, it is known that the temperature at which pressure is accurately given by the laws of a perfect gas at a particular volume, is constant for large volumes until critical volume is approached. The author observes that at the critical volume this temperature diminishes somewhat from its value for large volumes. These conclusions were embodied in a previous paper, and an algebraical expression for pressure in terms of temperature and volume were then given for isopentane. In the present paper the author investigates a similar formula for ether. Prof. Ramsay said that experimental errors might account for some of the lack of agreement between proposed formulæ and direct observation of the behaviour of gases. Isopentane was probably a better-investigated body than ether, for it was simpler. Ether tended to form complex molecular groupings, but isopentane was probably a mono-molecular liquid. Prof. Perry did not quite agree with the author's conclusions. It was necessary to distinguish between a formula founded on a physical hypothesis, and a mere empirical formula. The author had assumed that the Ramsay and Young formula was very exact, its originators did not put it forward as being infinitely exact. Probably the best test for such a formula as that under discussion would be derived from some thermo-dynamical conclusion deduced from it. The Rose-Innes formula, with five constants and implying discontinuity, was to be distrusted, for there was no such thing as discontinuity in the problem. In any case, an empirical formula should have a very simple form. Mr. Rose-Innes admitted that a formula founded on sound hypothesis was to be preferred to empirical expressions. But mathematicians had not yet provided an hypothesis applicable to a substance whose molecular arrangement was so complicated as that of ether. Mathematicians must, therefore, improve their methods before working formulæ could be deduced from their hypotheses. The use of an empirical formula with five constants was justified by Kepler for the planetary orbits. Kepler used that formula with no other justification than his experience that an ellipse fitted his observations better than a circle. Similar instances might be cited from recent work on the theory of solution, and osmotics. Mr. Johnstone Stoney was disposed to look for a mathematical cause for the cusp; it was improbable that the physical change was so abrupt as that represented graphically by the author. The question might be tested by plotting the two curves $y = v^{-\frac{1}{2}}$ and $y = a v^3$, and by observing whether these also suggested discontinuity.—Mr. W. L. Waters then read a paper on the variations in the E.M.F. of the H-form of Clark cells with temperature. The authors, Messrs. F. S. Spiers, F. Twyman, and W. L. Waters, have investigated how nearly the true E.M.F. of Clark cells can be computed at different temperatures by applying the ordinary temperature correction. As a standard, two cells of the Muirhead type are employed. The four cells under test could be put through cycles of temperature in a special heating bath, containing oil circulated by a centrifugal pumping vane. E.M.F.s were determined by a potentiometer method, and a careful study was made of the "lag" of E.M.F. behind temperature. The results are given in the form of curves. It is shown that "lag," in the H-form of cell, is less than in the "Board of Trade" form. Under ordinary conditions, when the rate of variation of temperature is less than 2° C. per hour, by applying temperature-corrections the true E.M.F. of the H-form can be found to within a ten-thousandth of a volt. In this respect there is little to choose between the H-form and the "Muirhead" cell. Mr. W. R. Cooper thought the authors did not express the case clearly. The E.M.F. of the "Board of Trade" cell could not, with reason, be itself stated within 1 per cent. But in some cases when, for instance, cells were used differentially, greater accuracy might be required, as, for instance, when a constant source of E.M.F. was being compared with the variations of another source. Here it might be necessary to know the "lag." He would like to know with what degree of accuracy the E.M.F. of the standard cell was determined by the authors. The lag that occurred in the "Board of Trade" cell was probably due to diffusion, crystallisation, and solution.—Mr. Waters said the E.M.F. of the standard was measured by a Kelvin balance to one in ten-thousand.

Entomological Society, November 3.—Mr. R. Trimen, F.R.S., President, in the chair.—Mr. Selwyn Image was elected a Fellow of the Society.—Mr. J. J. Walker exhibited specimens of *Anisolabis annulipes*, Luc., an introduced species of earwig taken among bones at the chemical works at Queenborough, and of *Brachysomus hirtus*, Boh., a rare weevil, taken among dead leaves at Chatham.—Mr. Janson exhibited a variety of *Melanargia galatea* of a clear yellowish cream colour, without trace of the usual black markings. It was captured between Dover and Walmer in 1843, and was still in very perfect condition.—Lord Dormer showed a remarkable openwork cocoon of an unknown Japanese moth, constructed from the larval hairs.—Mr. Jacoby exhibited fine examples of both sexes of the Australian Hepialids, *Charagia ramsayi*, *C. splendens* and *Hepialus daphnandri*.—Mrs. Nicholl exhibited a selection from the butterflies collected by her this year, in June and July, in the Albarracin Mountains in Aragon, containing several additions to the list of the district published in Madrid by Don Zapater and Herr Max Korb. The species of greatest interest were *Erebia zapateri*, Oberth., *Cœnonympha iphioides*, Staud., *Satyrus prieuri*, Pier., and its fulvous ♀ var. *uhagoni*, which was observed to be much more attractive to the males than the normal form was; *Argynnis hecate*, Esp., and *Parnassius apollo*, L., of which a female variety occurred with red-centred ocelli on the upperside of the forewing.—The Rev. H. S. Gorham showed examples of the following rare beetles from the New Forest: *Notiophilus rufipes*, *Velleius dilatatus*, *Trichonyx sulcicollis*, and *Lytta vesicatoria*.—Mr. Tutt showed a series of Noctuæ, taken at Romford by the Rev. W. Claxton, all of aberrant form; and for Mr. J. Merrin a specimen of *Aglais urticæ* with a silvery costal spot on the underside of the forewings, a series of *Melitæa aurinia*, and an example of *Syrichthus malvæ*, ab. *taras*, taken near Gloucester.—Mr. Kirkaldy exhibited a complete series of species of the genus *Notonecta*, L., specimens of the larva and imago of the very rare *Deinostoma dilatatum*, Say., from Arizona, and specimens of *Antipalocoris marshalli*, Scott, from Ceylon, which was previously recorded from Corsica alone.—Papers were communicated by the President on new or little-known species of African butterflies, and by Mr. E. Meyrick on new Lepidoptera from Australia and New Zealand.

CAMBRIDGE.

Philosophical Society, November 8.—The following communications were made:—On a method of demonstrating assimilation in green plants, by Mr. F. Darwin, President. Farmer has shown that the protoplasm ceases to circulate in an Elodea leaf subjected to a stream of hydrogen and kept in the dark; also that if the preparation is illuminated the circulation begins again. The cessation of the circulation depends on the protoplasm being deprived of oxygen, the reappearance of the movement is a consequence of the fresh supply of oxygen yield by the chloroplasts in light. The experiment can be more simply performed by mounting in water two or three Elodea leaves under a single cover-glass, and sealing the preparation with melted wax and paraffin. The leaves if kept in the dark begin after a few hours to suffer for want of oxygen, and after six or seven hours the protoplasm ceases to circulate. The movement may be restored by exposing the preparations to sunlight or to incandescent gas flame. Thus a demonstration, in its way as interesting as Engelmann's bacterial method, may be very simply performed.—Artificial cultures of *Stereum*, a timber-destroying fungus, by Prof. Marshall Ward.—On *Encephalartos ghellinckii*, Lem., a rare Cycad, by Mr. A. C. Seward. The author gave a short description of a plant of *Encephalartos ghellinckii*, Lem., which had been obtained by Mr. Lynch, of the Botanic Gardens, from Messrs. Saunders, of St. Albans. This species differs in the form of the frond from the better-known examples of the South African Cycadean genus *Encephalartos*, and presents certain features which are of importance from a palæobotanical point of view.

MANCHESTER.

Literary and Philosophical Society, November 2.—Mr. J. Cosmo Melvill, President, in the chair.—Prof. Boyd Dawkins, F.R.S., exhibited a section of a spruce trunk which had been completely hollowed out by a polysporous fungus. The resinous pine-knots, however, are left entire, radiating from the centre. He also pointed out that similar pine-knots (which he examined in the museum at Basle) found in the interglacial deposit of Darnten, and considered by Profs. Rütimeyer and Schwendauer to be the remains of old basket-work or wattle-work, and to prove the existence of interglacial man, are merely the result of the nature decay of the wood, and are not artificial. He also showed, under the microscope, a section of Fardel coal, showing a resinous stem or knot from a carboniferous plant, the rest of which has gone to form the black substance of the coal. Prof. F. E. Weiss made some remarks on the exhibit, attributing the destructive action to the fungus *Trametes pini*, and explained how the fungus attacked the centre of the tree, making its way in through the decayed core of broken branches.—Prof. Weiss then exhibited a specimen of *Plowrightia morbosa*, the black-knot, on a branch of cherry collected in Canada, where it has been the cause of considerable destruction of cherry-trees. He also exhibited the fructifications of *Peziza æruginosa*, the green-rot of the oak. The fructifications of this fungus, which are rarely met with, were collected at New Abbey, near Dumfries. A discussion followed, which also turned on the subject of the colouring-matter of fungi.—Prof. H. B. Dixon, F.R.S., exhibited and remarked upon a number of lantern photographs of explosion-flames.

PARIS.

Academy of Sciences, November 8.—M. A. Chatin in the chair.—On the influence of hygroscopic substances upon the combination of hydrogen and oxygen, by M. Berthelot. The hygroscopic substances chosen were hydrogen chloride, boron fluoride, and sulphurous anhydride as giving homogeneous systems for liquids, concentrated sulphuric acid; for solids, phosphorus pentoxide, baryta, quick-lime, and potassium hydroxide. Of these the three gases were found to be without appreciable effect in accelerating the reaction; with sulphuric acid, the hydrogen alone disappeared at 280°, owing to its reacting with the acid. In the case where phosphorus pentoxide was present, the rate of combination was of the same order of magnitude as when the mixture was heated alone. The conclusion is drawn that there is no equilibrium corresponding to the vapour pressure of the water produced, but that the reaction, although very slow, is unlimited.—On an explanation applicable to the phenomena of Faraday and of Zeeman, by M. Henri Becquerel. Starting from the hypothesis that in a magnetic field the ether possesses a vortex-movement of given period, θ, the conclusion is drawn that in the Zeeman phenomenon the variation of the wave-length ought to be proportional to the square of the wave-length. The value of the reciprocal of θ is calculated both from the Zeeman and Faraday effects, the numbers for air showing a good agreement in the two cases.—Study of the oysters of Cette, from the point of view of pathogenic micro-organisms, by MM. Ad. Sabatier, A. Ducamp, and J. M. Petit. No pathogenic organisms could be found in oysters after exposure for some time to water containing sewage. Even when cultures of the typhoid and *Coli communis* bacilli were injected into living oysters, no trace of either could be detected after four days in sea water. The authors conclude from these experiments that there is *no ground for considering oysters as one of the causes of typhoid fever.*—The Perpetual Secretary announced to the Academy the loss sustained by science by the death of M. Scheering.—Observations on the Perrine comet (October 1897) made at the Observatory of Algiers, by MM. Rambaud and Sy.—On the general theory of functions of real variables, by M. R. Baire.—On the potential of the double layer, by M. A. Liapounoff.—On the mechanism of rotatory magnetic polarisation, by M. André Broca.—On the variation of energy in isothermal transformations; electric energy, by M. H. Pellat.—The dissemination of the X rays, by M. Abel Buguet. By the use of protecting leaden screens, in cases where a long exposure is required, a much clearer photograph is obtained.—On the molecular volumes and densities of gases in general at all temperatures and mean pressures, by M. A. Leduc.—Table of the elements, arranged with the atomic weights in multiple proportions, by M. H. Wilde.—On some new lines in the spectra of oxygen and of thallium, by M. H. Wilde.—On the action of nitric acid upon tin, by M. R. Engel.—Estimation of phenylhydrazine, by M. H. Causse. The method proposed is based upon the reduction by the phenylhydrazine of arsenic to arsenious acid, and the iodometric estimation of the latter.—New combinations of phenylhydrazine with mineral salts, by M. J. Moitessier. The salts described are compounds of phenylhydrazine with the chlorides and sulphates of nickel and cobalt, and cobalt bromide. They contain more phenylhydrazine than the series previously described.—Biological preparation of levulose from mannite, by MM. Camille Vincent and Delachanal. The ferment of sorbose, developing in a solution containing mannite, oxidises the latter to levulose.—On some halogen derivatives of methyl-phenyl ketone, by M. A. Collet. The preparation and properties of

$$C_6H_4Cl.CO.CH_2Cl\ [1:4],\ C_6H_4Br.CO.CH_2Cl\ [1:4],$$
$$C_6H_4Cl.CO.CH_2Br\ [1:4],\ \text{and}\ C_6H_4Br.CO.CH_2Br\ [1:4]$$

are described.—On caroubinose and *d*-mannose, by M. Alberda van Ekenstein. The sugar described as new by M. J. Effront (August 2, 1897), obtained from the grains of *Ceratonia siliqua*, is identical with *d* mannose.—Vegetation with and without argon, by M. Th. Schlœsing, jun. No difference could be observed in the growth of the plants in the two cases, and no measurable amount of argon was absorbed.—On Strongylosis observed at the Agricultural School at Grignon, by M. Ch. Julien.—On the production of gum in the Sterculiaceæ, by M. Louis Mangin.—On the periods of development of the black rot in the south-east of France, by M. Joseph Perraud.—On the diseases of the bulbs of *Crocus sativus*, L., by M. E. Roze.—Researches on the formation of oil reserves in seeds and fruits, by M. C. Gerber.—On the absorption of carbon monoxide by the blood of a living mammal, by M. N. Gréhant. The experiments showed that for air containing 1/6000th of its volume of carbon monoxide or less, the volume absorbed by 100 c.c. of blood was proportional to the time. For stronger mixtures (·001) a limit appeared to be reached after about three hours.—On the histological modifications of nerve cells in a state of fatigue, by M. Ch. A. Pugnat. Fatigue in the nerve cells is accompanied by a diminution in volume of the cellular body and the nucleus, and by the disappearance of the chromatic substance of the protoplasm.—Intermediate forms in cartilaginous tissue, by M. Joannes Chatin.

VOLCANOES OF NORTH AMERICA.

Volcanoes of North America; a Reading Lesson for Students of Geography and Geology. By Israel C. Russell, Professor of Geology, University of Michigan, Pp. xiv + 346. (New York: The Macmillan Co. London: Macmillan and Co., Ltd., 1897.)

PROF. RUSSELL'S beautiful volume is, in some sense, a companion to Sir Archibald Geikie's account of the volcanoes of Great Britain; but whereas the latter deals with volcanic relics of all ages in an area the whole of which has been studied in considerable detail, the former has to do only with still active volcanoes, or such as have been in activity since the beginning of the Tertiary era, while in many of the districts dealt with but little scientific information is available.

The first chapter contains a most useful summary of the general characteristics of volcanic action all the world over, culled from the work of authorities like Judd, Palmieri and Shaler, Verbeek, Dutton and Dana, followed by an account of the shape and structure of cones, and the different rock products formed by volcanic action. American volcanoes do not enter much into this account, but touches of local colour are not altogether absent, for we learn that "while Vesuvius is regarded as a very obstreporous volcanic vent, its performances are mere Fourth of July fireworks in comparison with the Day of Judgment proceedings of Krakatoa."

In dealing with masses of intrusive rocks the author distinguishes between dykes, sills, laccolites, plugs, and *subtuberant* mountains, the last term applying to great sculptured domes like the Black Hills of Dakota, known to be based in an enormous core of granite which appears to have slowly increased in bulk like "the growth of a tuber in the earth" and lifted the sediments upon its back.

The next three chapters are devoted to the volcanoes of North and Central America. The author does not appear to have visited Central America, Mexico, or Alaska north of Cook's Inlet, and in his description he is further hampered by the absence in many cases of recent or trustworthy scientific information. Considering this disadvantage the account given is a very useful one, and as much care has been taken to exclude untrustworthy information as to make the most of what is good. In spite of Humboldt's authority, Prof. Russell thinks the story that Jorullo arose in a night is not worthy of credence. Izalco, in Central America, however, appears to have acquired its total height of 3000 feet above the surrounding country since 1770.

Passing on to the volcanoes of the United States, Prof. Russell at once finds himself at home and amongst examples which he has personally studied. His account becomes more graphic and full of the results of close and careful observation. Beautiful examples of denuded rocks standing as columnar rock pillars are associated with the lava sheets forming "mesas" or plains about Mount Taylor in New Mexico. The oddly-named Ice-Spring Craters in Utah seem as perfect as those of Auvergne, and illustrate some strange phases of eruption. The lake of molten lava in one of the craters appears to have slowly risen to a considerable height before breaking out an exit for itself, and relics of its former levels still exist in five terraces inside the crater ring. One of the lavas, too, though lying in a depressed channel, evidently "spread beyond its channel, like an aqueous stream, and deposited, not its sediment, but its crust."

Many interesting features of the craters near and in Monro Lake, California, are described; but we have only room for one or two of the observations. Granite pebbles occur in the tuffs, evidently thrown up from a gravel sheet through which the volcano burst; one of the lava streams when looked at from above is seen to have its scoria ridges arranged like curved terminal moraines; the lavas are mainly obsidians, and remain as plugs, more or less filling some of the craters, and even in certain instances rising higher than the crater rim without overflowing; where it did outflow, the lava was highly viscous, and was pushed forward in thick sheets, terminating in precipices between 200 and 300 feet high. The beautiful cone of Mount Shasta in California, of which a picture is given, has not been long extinct, for its most recent lavas are not glaciated. Yet one of them entered the cañon of the Sacramento River, reaching a distance of fifty miles, and the river has since cut through this barrier and excavated a narrow gorge more than a hundred feet deep in the rocks beneath. A still more remarkable case of erosion is quoted from an extinct volcano near Fort Union in New Mexico, where a lava filled up the Mora cañon to a depth of 400 feet. The river has re-excavated this channel, and cut down 230 feet into the rock beneath. "The time required for Niagara to cut its gorge . . . has been variously estimated at from 7000 to 35,000 years." "In comparison with Niagara, it is safe to say that 150,000 to 200,000 years have passed since the lava plunged in a fiery flood into the gorge of the Canadian [River]." The descriptions of Crater Lake, Oregon, and the extinct snow-clad giants of the Cascade Range, set amongst their dense forests like a "belt of emerald studded . . . with immense brilliants," must be passed over, as well as the admirable accounts of the vast lava fields of the Columbia and the volcanoes of the Rocky Mountains, though they are full of good points.

A chapter is devoted to the noteworthy deposits of volcanic ash and dust, some of which locally attain a depth of fifty feet, and spread over such areas as 10,000 and even 53,000 square miles. These indicate that "disasters similar to those accompanying the eruptions of Conseguina and Krakatoa occurred at intervals throughout the Tertiary and Recent history of fully one-half of North America," leaving their traces in tracts of fertile soil and deposits of considerable economic value.

In his chapter on "Theoretical Considerations," Prof. Russell adopts the idea of "potential plasticity" of the earth's interior. From this he derives the pressure which brings molten matter to the surface, relegating to quite a secondary place the influence of steam. For many reasons he considers steam an accidental and non-essential constituent of lava, obtained by it when coming into contact with water-saturated rocks. The association of volcanoes with ocean-margins he considers to be due to the fact that both classes of phenomena mark planes of weakness in the earth's crust. This chapter is well deserving of careful study, and the final one presents an interesting sketch of the chief events which mark the life-history of a volcano.

The book is carefully written, and well illustrated by maps and process-blocks from photographs. It would be a convenience if some simple mark had been used to indicate on the large map those volcanoes which have been active within recent times. W.

THE PRINCIPLE OF CONSERVATION OF ENERGY.

Das Princip der Erhaltung der Energie und seine Anwendung in der Naturlehre. Von Hans Januschke. Pp. x + 456. Medium 8vo. (Leipzig: B. G. Teubner, 1897.)

THOSE who are engaged in teaching applied mathematics cannot fail to appreciate the wide advantages arising from according greater prominence to the principle of conservation of energy than it obtained in the text-books of the last generation. Unfortunately, however, this principle, when stated in the restricted form in which it is most easily understood—viz. the mere assertion of constancy of the total energy, kinetic and potential, of a material system—is insufficient of itself to determine the actual motion of systems with more than one degree of freedom, and, moreover, cannot be applied to find the passive reactions arising from constraints. This particular point has been brought out forcibly in the recent controversy on "energetics" in which Boltzmann, Planck, Helm and others have taken part. Some further assumption or generalisation is necessary; either the principle of physical independence of force, or the extension of the principle of energy to virtual displacements (*i.e.* the principle of virtual work), or the hypothesis that the equation of energy holds good separately for every particle of a material system for the components of motion in every direction, or the assumption of the variational equation, or the principle of least action; all these alternatives are practically equivalent, and enable us to construct an energy theory of dynamics. Only quite recently Prof. Boltzmann, writing in *Wiedemann's Annalen*, suggested the possibility of building up the equations of motion, first of rigid bodies, and then of fluids and elastic solids, from the principle of energy aided by suitable subsidiary hypotheses; and the present volume is interesting as showing how this method works out when applied to a somewhat elementary text-book.

We fear that Herr Januschke hardly emphasises sufficiently the subtle difference between the restricted form of the principle and these necessary generalisations. At any rate, his deduction of d'Alembert's principle (p. 42) strongly reminds us of Clerk Maxwell's proof of the Lagrangian equations ("Electricity and Magnetism," vol. ii. § 561), the fallacy in which has been pointed out by Prof. J. J. Thomson. If we differentiate the equation of energy

$$W_0 + \Sigma(Fh + \tfrac{1}{2}mv^2) = \text{constant}$$

with respect to the only independent variable, the time t, where $dh/dt = v$, we obtain

$$\Sigma\left(F\frac{dh}{dt} + mv\frac{dv}{dt}\right) = 0,$$

whence, by taking account of the fact that (according to Herr Januschke) dh and dv are of opposite signs, it is possible to write down the equation

$$\Sigma\left(F - m\frac{dv}{dt}\right)dh = 0.$$

But here $dh = vdt$, and so the variations dh are not all independent, but their ratios are connected by relations of the form

$$\frac{dh_1}{v_1} = \frac{dh_2}{v_2} = \frac{dh_3}{v_3} = \ldots$$

There is here no justification for the inference that such an equation will hold for variations other than such as are connected by this relation, *i.e.* for displacements other than those the body really undergoes. As regards the change of sign mentioned above, comment is superfluous.

In treating projectiles, the principle of independence of motions is assumed, and with this aid no difficulty occurs. But we naturally pass on to the treatment of "centrifugal force" as a more crucial test of the energy method, and here we find the result obtained either by a wholesale disregard of algebraic signs, or at any rate by what appears to an ordinary reader as such. Taking two particles m_1 and m_2 connected by a string of length $r_1 + r_2$ and revolving in circles of radii r_1 and r_2, the kinetic energy is

$$W = \tfrac{1}{2}m_1v_1^2 + \tfrac{1}{2}m_2v_2^2.$$

For equilibrium the author writes down from this:

$$dW = m_1v_1dv_1 - m_2v_2dv_2 = 0$$

(why the sign of the second term should be changed is not obvious). Hence he infers that the tension in the string is,

$$p = m_1v_1\frac{dv_1}{dr} = m_2v_2\frac{dv_2}{dr}.$$

Putting $v = rw$ where w is the angular velocity, he gets for the centrifrugal force,

$$p = \frac{m_1v_1^2}{r_1} = \frac{m_2v_2^2}{r_2}.$$

This result is obtained on the supposition of v being directly proportional to r. But in the theory of central orbits, it is known that unless work is done on the particle by tangential forces, the angular momentum, and not the angular velocity, is constant, and hence v ought to be taken inversely proportional to r, which would reverse the sign of the result. Hence Herr Januschke's method really makes the normal acceleration tend in the wrong direction.

After dealing with rigid bodies, the equilibrium and motion of fluids are considered; but this portion does not extend to the general equations of hydrodynamics (where we should have most liked to see how the "energetic" method works out), Torricelli's theorem and the hypothesis of parallel sections being alone considered. Gases follow next, then a chapter on "molecular forces" dealing with elasticity and capillarity. Chapter v. deals with heat, and includes a very fair exposition of the first and second laws of thermodynamics, the subject being opened by a simple mechanical analogue, by means of which the conception of absolute temperature is introduced. The determination of specific heats, properties of gases, change of state, Van der Waals's equation, and the critical point are well treated, and an attempt is made to explain the phenomena from the molecular standpoint, so far as this can be done by general reasoning. The author's treatment of thermodynamics, however, does not present any striking divergence from the conventional standpoint in which conservation of energy necessarily occupies a prominent position. Of the chapters on electricity, magnetism and light, we can only say that they appear to form a concise and convenient introduction to the elementary principles of the subject.

As an introductory sketch of the outlines of natural philosophy, the book may be unhesitatingly recommended. The wide range of ground covered renders the treatment somewhat encyclopædic, but a notable feature is the large amount of historical information with which each chapter opens. This alone makes the volume valuable as a work of reference.

Another excellent feature is the large number of examples on nearly every section. Many of these are straightforward numerical calculations based on the bookwork, nearly all of them illustrate some point of physical interest. But it is a pity that the student after reading the question sees the answer before him, instead of having an opportunity to work it out for himself; these answers would be much better placed at the end of the book.

Whether Herr Januschke has succeeded or not in establishing the superiority of the "energetic" method, there can be no doubt that he has produced a text-book which will prove of great use to students, and still more to teachers of physics. G. H. BRYAN.

THE FERTILITY OF THE LAND.

The Fertility of the Land. By Isaac P. Roberts. Pp. xvii + 415. With forty-five illustrations. (New York: The Macmillan Company. London: Macmillan and Co., Ltd., 1897.)

THE sub-title of this volume, "A summary sketch of the relationship of farm-practice to the maintaining and increasing of the productivity of the soil," conveys a comprehensive idea of its scope. It belongs to the Rural Science Series, and Mr. L. H. Bailey, who contributes the preface, bestows upon the book a sort of editorial benediction when he commits himself to the statement, "It is the ripened judgment of the wisest farmer whom I have known." The editor further remarks,

> "I confess that I have looked with some apprehension upon the rapid diffusion of experimental science of recent years, for there is danger that this knowledge may overshadow the importance of accustomed farm-practice, and lead the farmer to demand specific rules for each perplexity, and to depend upon the Experiment Station and the teacher for his farming."

The fifteen chapters deal with the following subjects: (1) an inventory of the land; (2) the evolution of the plough; (3) tilling the land; (4) conservation of moisture; (5) irrigation and drainage; (6) farm manures; (7) manures produced by various animals; (8) the waste of manures; (9) the care, preservation and application of manures; (10) nitrogen and nitrification; (11) the phosphoric acid and potash supply; (12) commercial fertilisers; (13) lime and various amendments; (14) green manures and fallows; (15) rotations. The treatment of the subject is thus seen to be fairly discursive, and the omission of, for example, the second chapter on the evolution of the plough would in no way have detracted from the main object of the volume. It may be noted in passing that the part of the implement which is familiarly known in this country as the skim coulter is designated the "jointer or skim plough" by the author; we think the English name is preferable as being more descriptive. Much valuable information is brought together in the volume in a convenient form, whilst most of the assertions made by the author, though they may not always carry conviction, are suggestive in character and calculated to stimulate useful trains of thought in the student's mind. The chief defect of the volume is that it ignores the epoch-making work in which Lawes and Gilbert have been engaged for more than half a century. Neither their names nor the name of Rothamsted are mentioned in the index, nor do we come across any reference to them in the text. As the author, we are told, "has had the advantage of much travel," we can only suppose this omission is intentional. The book, of course, suffers in consequence; to give only one instance, the author has missed entirely the admirable definitions of "fertility" and "condition" as applied by Lawes to the soil, and as usefully adopted for practical purposes by English farmers. That the writer is not altogether successful in his selection of authorities is further apparent from the circumstance that he betrays no knowledge of the researches of Warington in nitrification. There is evidence, however, of much familiarity with continental work, and the title of the thirteenth chapter, "lime and various *amendments*," has an unmistakably French flavour. The book is well printed and neatly turned out; but the Englishman who respects his mother-tongue will experience a shudder at the strange spectacle presented by certain familiar words spelt in "American."

CRIME AND CRIMINALS.

Crime and Criminals. By J. Sanderson Christison, M.D. Pp. 117. (Chicago: The W. T. Keenen Company, 1897.)

DR. CHRISTISON has been attracted to a subject full of difficult problems, but he makes no very practical contribution to their solution. He is a student in the school of Lombroso, and has been at some pains to investigate the psychological aspects of the criminal The cases he presents are, many of them, interesting enough; but beyond proving the fact that the types of offenders are much the same all the world over, they serve no particular purpose, and they are certainly not sufficient to justify the main point of his book—that our existing penal methods are a failure. He has been helped to this conclusion, moreover, by the single experience of the United States where, in his own words, "crimes are now nearly five times as numerous as forty years ago." The criminal statistics of other countries, notably of England and Belgium, can happily show different figures, judging by the numbers incarcerated now and in previous years, the only trustworthy test indeed. Dr. Christison seems inclined to lay too much stress upon prison systems as affecting the increase and decrease of crime. Where they are manifestly bad, as it is to be feared they are in a very large proportion of cases in the United States, they may manufacture criminals. For example, there is no more fruitful source of crime than the indiscriminate association of prisoners of all classes and categories which is still very general in American prisons. For one Elmira, with its ultra-tenderness for the dishonest, there are hundreds of county gaols where no sort of care is taken to separate the inmates, whether young or old, innocent or guilty; and it is where this separation has been most strictly enforced, as with us, that crime has most appreciably diminished.

But the penal system, however carefully and intelligently worked, is but a small contributory cause to reduction. That is to be found rather in the newer and more enlightened processes of deferred sentences for first offenders and of systematic child rescue, both based upon the excellent principle that crime should be checked in the bud. Dr. Christison enunciates a truism when he declares that crime is frequently associated with bodily and brain disease. No one denies this; it is, too often the poor invertebrate creatures who have no sinew, moral or physical, who lapse into misdeeds, and they deserve pity rather than punishment. But these do not make up the sum total of the great army of crime; they do not include the stalwart, able-bodied habitual criminal—the real crux of modern penology—who has adopted law-breaking as a business, and whom nothing, humanely speaking, will cure. To apply Dr. Christison's kindly milk and water treatment to these would be a mischievous misuse of the power of the law, the first duty of which is to protect the law-abiding from the law-breaking. The habitual criminal should have neither truce nor peace. Penal science is fast tending to establish the somewhat paradoxical apothegm of a well-known writer who has said that offenders may be divided into two great classes: "those who should never go into prison and those who should never be let out"; the first offender who should be left at large on condition that he does not again go wrong, and the habitual criminal who is retained indefinitely, or until he gives reasonable promise that he will not persistently misuse his freedom.

OUR BOOK SHELF.

Chauncy Maples, D.D., F.R.G.S. A Sketch of his Life, with Selections from his Letters. By his Sister. Pp. 403. (London: Longmans, Green, and Co., 1897.)

THE publication of this memoir of Dr. Chauncy Maples—a pioneer missionary in East Central Africa for twenty years—reveals that sympathetic interest in science which has been strikingly noteworthy in some of the most remarkable missionaries of our time. In 1881 Mr. Maples, then stationed at Masasi, made a journey of 900 miles to the Meto country, and in this and other ways contributed to our knowledge of the geography of East Africa. His papers were appreciated by the Royal Geographical Society, of which he was a Fellow. And he quite entered into the spirit of the recent development of Nyasaland at the hands of the British administrators, founding and editing the *Nyasa News*, which was printed on the island of Likoma by his native boys. Sir Harry Johnston, K.C.M.G., contributed to it, and writes cordially of the late Bishop in his recent book on "British Central Africa." Sir Harry was almost the last European to see him alive; for a few days afterwards he was drowned in the Lake Nyasa, September 3, 1895, on his way to his post. In the Bishop's last letter but one, written, of course, before the knighthood, he says: "I was more struck than ever with the Commissioner's cleverness and accomplishments and his power of doing so many things, as he does, so very well. He is certainly a very remarkable man indeed."

On the other hand, Mr. G. F. Scott-Elliot, a scientific traveller well known to the readers of NATURE, looked upon Chauncy Maples as "an ideal missionary," and described him as "one whose sympathies extend even to Europeans." Several times in the letters now published reference is gratefully made to the geological works of Sir Archibald Geikie. In a private letter dated Likoma, March 14, 1888, Archdeacon Chauncy Maples has the following striking and sympathetic reference to Charles Darwin:—

> "It would seem that part of his nature adapted to the reception and cultivation of religious truth got atrophied by disuse, and hence his discarding of Christianity. These things are great mysteries, and when we think of so great and really good a man as Darwin was, we ought to avoid all appearance even of seeming to know *how* he stood in God's sight when his probation was over and his soul returned to God who gave it. . . . Another great point about Darwin was that he never did or said anything that could be construed into a desire to disturb the faith of others; if evolution has disturbed it, it is their fault and not his. I confess to having a good deal of belief in evolution; but it has never disturbed my faith in revelation—no, not one jot" (p. 294).

The late Bishop was, like the friend and colleague who has succeeded him as Archdeacon, the Rev. W. P. Johnson, a graduate of University College, Oxford. His successor, the present Bishop of Likoma, Dr. J. E. Hine, is also an Oxford man, having graduated in science both in Oxford and London. Of the latter University he is M.D. It is also remarkable that another South African Bishop had a distinguished scientific career, both at London and Cambridge. The Bishop of Bloemfontein, the Right Rev. J. W. Hicks, is Doctor both of Medicine and of Theology. He is M.D. Lond., D.D. and Sc.D. Camb., and late Fellow and Science Tutor of Sidney Sussex College, Cambridge.

J. F. H.

Les Ballons-Sondes. Par M. de Fonvielle. (Paris: Librairie Gauthier-Villars, 1898.)

WITHIN the last seven years a new epoch has dawned upon the science of aerial travel and investigation.

While the more directly practical advances in flying machines and balloon navigation have caught the popular fancy, a less conspicuous but more valuable means of extending our present knowledge of atmospheric physics has been supplied by the recently organised flight of small, specially constructed balloons provided with self-recording apparatus which, without the deterring weight of observers, have been able to explore regions of the atmosphere far beyond the limits of human endurance.

M. de Fonvielle, the celebrated French aeronaut, has brought together the results so far attained in a neat little brochure entitled "Les Ballons-Sondes," or "sounding balloons." Perhaps "exploring balloons" would be a freer and more euphonious translation.

Here we have in four chapters a clear and simple account of these experiments from the earliest attempts of MM. Hermite and Besançon, the chief pioneers of the movement, to the latest ascents under the auspices of the International Committee in November 1896.

Perhaps the most interesting and suggestive chapter is that which deals with the theory of the ascent of an exploring balloon.

The results of the recent simultaneous international flight of aerophile balloons are also very suggestive.

The possible limits attainable by balloons are shown to depend quite as much on the character of the envelope as on the contained gas. Here also, for the first time, we find a clear exposition of the effect of the temperature of the gas over that of the surrounding air, and the "Montgolfier" effect of solar radiation in altering the height at which the balloon finds itself in neutral equilibrium.

When it is found that winter and summer can cause a change of 6000 feet, and day and night one of 8000 feet in the altitude attainable on the pressure theory, it must be recognised that the science of exploring balloons is far from simple.

The scientific value of such ascents, reaching as they have done already in the case of the "Cirrus" to 60,000 feet, or double that hitherto attained by man (Mr. Berson's 30,000 feet in the "Phœnix," December 1894), is undoubted, and M. de Fonvielle deserves the thanks of the scientific world for his lucid and fascinating account of a scientific art which is even more necessary for the advance of terrestrial and cosmical physics than the soundings of our deep-sea exploring ships. D. A.

A Geological Map of the Southern Transvaal. By F. H. Hatch, Ph.D., F.G.S. (London: Edward Stanford, 1897.)

THIS map, on the scale of four miles to the inch, will be useful to prospectors and those interested in the general geology of the district. The names and boundaries of the farms are given, and the geological map is accompanied by a physical map of the Transvaal.

The geological formations are broadly sketched in; the Witwatersrand, Black Reef and Megaliesberg series are represented as forming a trough let in by faults between a mass of primary rocks. The sections across country show a simplicity of structure for the Witwatersrand district with some complications by faulting north of Parys. The Witwatersrand beds are considered to represent the Table Mountain Sandstone and the Megaliesberg or Gats Rand series to be equivalent to the Zwartebergen Sandstone group.

The extent to which the beds are interfered with by volcanic rocks can be seen from the map. Besides the interbedded flows of basalts and diabases, a large area west of Klerksdorp is represented as composed of rhyolitic and andesitic flows, and north of the Megaliesberg Range and north-east of Pretoria there is a wide tract coloured as gabbro. The igneous flows of Pre-Karoo age are confined in Cape Colony to formations older than the Table Mountain Sandstone, so that if the age of the Gats Rand beds is correctly determined, the southern Transvaal exhibits a volcanic phase unrepresented in the Cape.

Untersuchungen über das Erfrieren der Pflanzen. By Prof. Dr. Hans Molisch. Pp. viii + 73. (Jena: Fischer, 1897.)

IN "Untersuchungen über das Erfrieren der Pflanzen," Prof. Molisch recounts his experiments on the cooling and freezing of plants. Dr. Molisch has worked over much of the old ground, and his observations, in the main, confirm those of previous workers. A comparison of the results obtained by Dr. Molisch with those set forth in the admirable summary in Pfeffer's "Pflanzen Physiologie," will show that the volume under notice contains little that is absolutely new.

By means of an improved apparatus, Dr. Molisch has examined the effects of freezing and thawing on such substances as starch-paste, gelatine, albumin and protoplasm. His conclusions confirm and extend those of Vogel and Kühne. As in the above-mentioned organic substances so in the protoplasm, *e.g.* of an amœba, freezing induces a reticular structure whose meshes contain pure ice. In many instances, however, ice formation only occurs, as is well known, outside the cell. Attention may, in passing, be drawn to the statement (p. 19) that, "to some extent," the smallness of plant cells represents "a means of protection against cold": were it not for the fact that the remark is considered worthy of repetition, it might have been regarded as intentionally ironical. As it is, it must be inferred that Dr. Molisch wishes to be numbered with the ultra-adaptationists.

Sachs had inferred, from observations on the relative rates of mortality in plants slowly and quickly thawed, that it is not the frost but the thaw that kills. H. Müller-Thurgau has shown this not to be generally correct. Dr. Molisch confirms H. Müller-Thurgau.

The most interesting of Dr. Molisch's experiments are those which prove that the withering of plants exposed to cold, although accompanied by, is not due to a slowing of the transpiration-current.

The practice of embodying a research in a volume intended for the public and the specialist alike is, where the results are of high generality, excellent; where, however, as in this volume, the results appeal primarily, if not solely, to the physiologist, and where the net is spread wide by rendering the meshes diffuse, fellow workers are entitled to protest. The "literature" is already a heavy burden and grievous to digest.

Random Shots at Birds and Men. By "Jim Crow." Pp. 117. (Westminster: The Roxburghe Press.)

THIS paper-covered booklet needs no extended notice from us. It is made up of very fugitive thoughts on birds, and moralisings on the ways of men, and is not, we should think, likely to interest either the student of science or the general reader.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Some Errata in Maxwell's Paper "On Faraday's Lines of Force."

IN translating this paper of Maxwell for Ostwald's "Klassiker der exacten Wissenschaften," I have detected some errors, which are partly merely misprints, but partly also faults in the formulæ of some trouble to the reader. The German translation is only of value to those who have not leisure to study the English language before the works of Maxwell; but the accuracy of such classic works is so essential to every one, that I considered the publication of the errata found to be of even greater importance than my whole translation. But in order to make the translation as cheap as possible, the German editor refused to print my list of errata, and I therefore hope it will be printed in England.

Finally, if Maxwell and the editor of his works have not avoided some troublesome errors, I do not wish to apply the *quod Jovi licet, non bovi licet*, to Mr. Curry's new book, "Theory of Electricity and Magnetism" (Macmillan, 1897), but to excuse some errors therein.

In the following table the first column gives the place of the misprint in the *Cambridge Philosophical Transactions*, vol. x. 1856; the second in Maxwell's "Scientific Papers," vol. i.

Vienna, October 25.

LUDWIG BOLTZMANN.

The Late Dr. Haughton.

IN your account of the late Dr. Haughton, as well as in those written of him elsewhere, I see no mention of a somewhat fantastic instance of his versatility—namely, his investigation into the most merciful way of hanging criminals. It was, I believe, entirely owing to him that the present method of the "long drop" was introduced. According to the older method the rope was so arranged that the culprit fell barely knee deep, all the rest of his body being in view above the scaffold. He died usually by strangulation, sometimes combined with apoplexy, after what seemed to be a protracted agony Now, he is allowed to fall through some 10 feet, more or less, according to his estimated bulk and weight, and he dies with a broken neck more painlessly than virtuous persons in their own beds. The problem was to find out the length of drop that would suffice to break the neck bone, but would be insufficient to tear off the head. Dr. Haughton experimented on the tensile strengths of the spine and of the muscles, and he published a formula for the length of drop, dependent on the height and weight of the culprit. In this, I thought he had omitted a small factor, and wrote to him about it—namely, the increased sectional area the muscles of the neck in fat men. It should be mentioned that a case actually occurred in which the drop was too deep, and the head of the criminal became wholly detached, and the legal doubt arose whether under those circumstances the sentence of being "hanged by the neck" had been duly carried out. I regret much that I have to write wholly from memory now, which I trust has not deceived me. It is very possible that Dr. Haughton's formula may be found in one of the earlier numbers of NATURE.

F. G.

The Supposed Dowsing Faculty.

PERMIT me to guard your readers against a misapprehension likely to be caused by the review in NATURE of October 14, of an investigation I have recently published on the alleged existence of a faculty for finding underground water, a power claimed by certain persons called "diviners" or "dowsers."

The reviewer states twice over that the "bulk of the paper is taken up with hearsay evidence," and again that it is "an accumulation of second-hand evidence," and that I do not give "enough weight to the natural tendency of mankind to conceal their failures." If these statements could be justified I should agree with your reviewer that my investigation "leaves the subject in the same state as it found it." But the peculiar meaning your reviewer attaches to the words he employs, and hence the value of his opinion, may be inferred from the following facts:—

Six years ago I was asked by the Council of the Society for Psychical Research to examine this question. I had, therefore, in addition to experiments which I myself conducted, to take the place of a judge in a court of inquiry, and give weight to no evidence but that of *eye-witnesses*; and so, in almost every one of the 152 numbered cases *pro* and *con* that are given in my paper, I quote such written and signed evidence, independent of the dowser himself. These witnesses are mostly men of good position, or wide experience, and to whom the question of obtaining water was a matter of practical importance and pecuniary outlay. The argument that some of them were biassed is a perfectly fair criticism, if true, but the bias was usually more on the side of incredulity than of credulity; take, *e.g.* the extreme scepticism of Mr. Richardson, the employer in the remarkable Waterford case, and of Sir Henry Harben in that at Warnham.[1] No evidential value is attached in my paper to any case not fully corroborated, and out of scores of such cases received some half-dozen have been published, as is expressly stated in my paper, in order to elicit further information on account of their intrinsic interest.

---

[1] It may well be urged that a man would not employ a dowser unless he were already biassed in his favour. But the gentlemen named above, and several other witnesses I have cited, consented to this course, either to gratify their friends, or as a *dernier ressort*, only after scientific advice and large expenditure on boring had failed to find the water supply they needed. Their attitude towards the dowser when he arrived was that of ill-disguised contempt. *How far "lucky hits" or "mother wit"* can explain the dowser's success in these and other cases, the reader of my paper must judge for himself.

As regards the liability to overlook failures, I have referred to this point both at the outset of my paper (p. 4) and elsewhere; further (on pp. 238 and 239), I state: "It must be borne in mind that (especially among amateur dowsers) one is more likely to hear of success than failure, and therefore an extensive and searching inquiry is necessary before any safe induction can be drawn. . . . All that was possible in the present investigation was to make the range of evidence as wide and unbiassed as possible, and not exclude a single case of failure that was substantiated. This has been done." It is, of course, easy to select, as your reviewer does, a certain number of cases in which the failures exceed the successes.[1] But I think one is more likely to arrive at a correct estimate by the method I adopted, which was to make extensive inquiries, both generally and specifically, with regard to failures as well as successes in the case of every professional dowser I heard of. This is naturally a vastly more laborious method than your reviewer's, but was necessary in order to arrive at the actual facts in a subject which from all sides has been loosely discussed, albeit by eminent men, for upwards of 200 years.

I am glad to find your reviewer endorses certain cautions I suggested in the event of further investigation; though what he means by "thought-reading" as a source of error is not quite clear. It is a matter of importance, more so than your reviewer appears to imagine, to recognise, and if possible exclude, the aid which the dowser derives from indications given by the surface of the ground. Long practice may give the most illiterate person a power of detecting surface indications of underground water, or the faint tremor of unseen running water, that would entirely escape the ordinary observer, and of enabling correct inferences to be drawn even from indications that the dowser may have noticed quite unconsciously. We have here, doubtless, the explanation of some of the singular successes of dowsers in finding water; but a careful examination of the evidence I have collected has led me to think that no explanation hitherto suggested is adequate to account for all the facts.[2]

Kingstown, Co. Dublin, October 21. W. F. BARRETT.

At the head of Prof. Barrett's memoir is the following quotation from Mr. Andrew Lang: "There are two ways of investigating the facts or fancies about the divining rod. One is to examine it in its actual operation—a task of considerable labour, which will doubtless be undertaken by the Society for Psychical Research; the other, and easier way, is to study the appearances of the divining wand in history." This naturally led me to think that Prof. Barrett intended to treat the subject as, in the main, a matter for personal investigation. He now claims, however, "to take the place of a judge in a court of inquiry." I therefore withdraw the term "hearsay" applied to the bulk of the evidence he has so laboriously collected, and will accept his own view of his position.

But Prof. Barrett will agree with me that this is a technical investigation needing expert knowledge. Now if so, where does the necessity for expert knowledge come in? Surely not after the experiments have all been made, and the dowser is off the scene; but, as in any other scientific investigation, on the spot, with the man and the conditions all before you. This is the very core of the investigation, and no amount of after analysis can atone for the lack of *personal* observation and judgment exercised at this, the crucial point. But here, where expert knowledge and observation are essential, he relies on others, of whom the majority have no previous knowledge or scientific training whatever.

Prof. Barrett "had to exclude all evidence but that of *eye-witnesses*." As to his "152 numbered cases," 9 are avowedly supplied by people who, on their own statement, do *not* appear to be eye-witnesses. In 41 more there is nothing to show whether his informant met the dowser himself, or is trusting to information received from others. The information in 8 of these comes from a firm or joint-stock company; 8 are merely newspaper reports; some are ancient cases, which cannot now be inquired into.

With reference to the statement regarding liability to overlook failures, I did not state or wish to imply that Prof. Barrett had not fairly given all the failures which came to his knowledge. What I did wish to imply was, that his method of writing to the parties concerned for evidence on this point was not likely to yield much result.

As to the Isle of Wight, I may say, that not making it a habit to collect information regarding the employment of dowsers in different districts, I merely alluded to one where I happened to have stumbled upon facts bearing on the question. Whether or no other districts would give similar or contrary results I cannot say, having no material to go upon.

I fail to understand what meaning Prof. Barrett attaches to the term "surface indications." He agrees with me as to their great importance; yet there are only 32 cases in which his informants make even the slightest reference to this subject, and in only 8 is there any note that Prof. Barrett made special inquiries on this all-important point.

As previously stated, my criticisms apply to the bulk of the evidence. I thoroughly recognise the value of Prof. Barrett's personal observations, and have only to regret that these experiments form so very small a part of his memoir.

THE WRITER OF THE ARTICLE.

A Proposed Memorial to Prof. Victor Meyer.

THERE appears to be a strong desire among many of the British students who worked under the late Prof. Victor Meyer, to give expression to the feelings of gratitude and admiration with which they remember him, by raising some form of memorial to be placed in the Heidelberg Lecture Theatre.

It has therefore been decided to call a general meeting of Prof. Meyer's British students, to be held in Manchester on Saturday, December 11, at 5 p.m. Prof. H. B. Dixon, F.R.S., has kindly placed the Organic Lecture Theatre of Owens College at our disposal.

All past students of the late Victor Meyer, whether they worked with him in Zürich, Göttingen or Heidelberg, are earnestly requested to be present.

I shall be pleased to receive suggestions from any who may be unable to attend, in order that they may be laid before the meeting. J. J. SUDBOROUGH.

University College, Nottingham, November 23.

The Critical Temperature of Water.

CAN any of your readers tell me what is the critical temperature of water. I find in the supplement to Jamin and Bouty's "Cours de Physique" the critical temperature given as 370° C. and the corresponding pressure as 195·5 atmospheres. On the other hand, Cagniard-Latour gave this temperature as equal to the melting point of zinc, which is known to be about 415° C.

I have some theoretical grounds for believing this latter figure to be the more accurate, so should be glad to know what other determinations, if any, have been made. H. M. MARTIN.

39 Guildford Street, W.C., November 19.

Coccoliths in our Coastal Waters.

IN our communication to NATURE, September 16, 1897, we say "the presence of these bodies (coccoliths) in our coastal waters does not appear to have been recorded." Since this was written we find that Dr. Wallich, in the *Ann. and Mag. of Natural Hist.*, vol. ii. 1868. p. 319, stated "Coccospheres have been met with by me profusely . . . in material collected at the surface of the open seas of the tropics, and also in dredgings from shoal water off the south coast of England"

Phenomena Exhibited by Jackson Tubes.

WHILE investigating the best methods of working the ordinary form of Jackson tubes during the last fourteen months, I have noted the following interesting phenomena.

Four tubes developed a phosphorescent ring or halo rotating rapidly round the anode, which by carefully heating became comparatively steady; this I ventured to name the Saturn condition.

---

[1] The reviewer is, however, delightfully free from the pedantry of those who think accuracy desirable when dealing with such a contemptible superstition as the so-called divining-rod. This, I think, is apparent already; it becomes more so when specific assertions of his are examined, such *e.g.* as "only two successes are mentioned in the Isle of Wight," &c.

[2] That a mixture of crass ignorance and charlatanry is to be found in many professional dowsers, and that some of them are little better than rogues, is only what might be expected; but, on the other hand, we have the fact that so distinguished a *savant* as M. Mortillet was once, as he tells us himself, a professional dowser, and published a book on water-finding in 1849. The President of the Royal Geological Society of Cornwall is still a successful amateur dowser.

Four tubes developed in bulb broad bands of light yellow-green electrical molecules, interspaced with darker bands; this was like the marking of the planet Jupiter.

Two tubes developed a mottled and leaf-patterned electric-molecular condition, extremely like the appearance of the photosphere of the sun (for the first time the skin of my hand was affected by one of these tubes—November 1896; this hand having some years previously had gouty eczema; the other hand was not affected in either case).

Two tubes developed forms like the clouds known as "mares'-tails"; one tube, a form like the sulky lower strata of distant thunder-clouds.

The most interesting phenomenon was one which was also seen by a medical friend: the whole tube was a mass of yellow-green phosphorescence, even behind the kathode; the molecular film in glass bulb in front and round the edge of the kathode (mottled condition) developed a small black spot the size of a pin-head, which increased to the dimensions of a small pea, broadened out into an irregular patch, split up into small spots, which ran round the bulb, disappeared; reformed into a patch—diminished—and disappeared. The phenomenon was repeated at regular intervals for ten minutes, then finally stopped. The irregular patch was extremely like a sun-spot.

From time to time I have called the attention of interested friends to the above phenomena, so as to have witnesses, as the tubes seldom repeat the same conditions, which can only be attained by the application of heat while working the tube.

The rays magnetised my watch on two occasions; an induction coil having no magnetic field, owing to interrupted current, could not do this. WILLIAM WEBSTER.

Art Club, Blackheath.

REMARKABLE TERMITE MOUNDS OF AUSTRALIA.

THE destructive propensities and architectural endowments of the termites or white ants are familiar subjects to most travellers and residents in tropical countries. Notwithstanding, however, the almost cosmopolitan distribution within tropic areas of these insect pests, an astonishingly small amount of accurate data has been chronicled concerning their specific varieties or the widely varying modifications of their social tenements.

As a matter of fact the figures and descriptions of the insects and nest mounds or "termitaria" of the African white ants *Termes bellicosus*, *T. mordax*, and other species contributed by Henry Smeathman to the *Transactions* of the Royal Society for the year 1781, constitute up to the present date the standard account of white ants and their ways that is reproduced with trivial variations in most modern zoological text-books. Much, undoubtedly, has been accomplished within recent years, notably through the investigations of Grassi and Sandias, Fitz Müller, and other biologists to elucidate the minute anatomy, individual modifications, and social economy and relationships of the indigenous or imported South European types *Termes incifugus* and *T. flavipes*. Neither of these forms, however, are mound constructors, but live within subterranean tunnels or in excavations of the wood which they devour. Smeathman is hence still left, *facile princeps*, the first, almost the only authority on the architectural fabrications of the mound-constructing species.

While Africa in connection with Smeathman's investigations has hitherto inherited an undisputed monopoly in the matter of termite mounds, it will probably be found that the island continent of Australia can produce an equally, and in some respects even more noteworthy variety of these insect edifices. So far as altitude is concerned, the palm among the Australian series must be conceded to the huge buttressed columnar termitaria that occur some forty miles inland from Port Darwin in the Northern Territory of South Australia. A height of at least eighteen feet is not unfrequently attained by this variety, and their diameter being almost equal throughout, their appearance has been appropriately likened to miniature towers. Termitaria almost equal in altitude to this Port Darwin variety have also been observed by the writer in York Peninsula, North Queensland, and are notably abundant on the point of land abutting upon the mainland foreshore of the southern entrance to the Albany Pass. The largest termitaria of this type occur, however, in the vicinity of the bridle path between Mr. Frank Jardine's homestead at Somerset, and the former telegraph station at Patterson facing Endeavour Strait. Passing them on horseback, many of these mounds were observed to tower considerably above the rider's head. The contour of these York Peninsula termitaria differs essentially from that of the Port Darwin form. In place of being subcylindrical or columnar, they are distinctly pyramidal, widest at the base, and tapering up to a single, or it may be occasionally several accuminate points.

Within the tropical area of Western Australia, known as the Kimberley district of that colony, a third large and very distinct type of termitarium is dominant. While most commonly presenting a symmetrically conical or hemispherical contour, it not unfrequently happens that these white ant mounds are built up into the most irregular and fantastic shapes. Throughout all such innumerable modifications, however, one essentially unique fundamental plan of structure is predominant. This is exemplified by the circumstance that each nest mound or termitarium presents the appearance of having been built up, as it were, by the superposition of consecutive hod-loads of half solidified mortar, and which before setting has partly overflown and overlapped the preceding instalments.

This lobulated or Kimberley type of termite mound, as it may be designated, occurs in great abundance and in its finest development in the thinly wooded scrub or so-called "pindan" in the neighbourhood of Derby, at the head of King's Sound. One of the tallest of these termitaria was found to measure as much as fourteen feet, but this altitude is occasionally exceeded. The separate occasions on which the writer visited King's Sound were utilised by him for obtaining information concerning the approximate time that is occupied by the termites in the reconstruction of a partially dismantled edifice. Examples of termitaria about eight feet high were bisected vertically, the one half being completely demolished. Within twelve months one quarter of the denuded area had been filled in. Visited eighteen months later, fully two-thirds of the demolished moiety had been rebuilt, and it would evidently have not taken more than another twelve-months, or a total of between three or four years, to restore the mound to its original symmetrical shape and dimensions.

The most remarkable, though by no means the most lofty of the termite edifices peculiar to Australia, are those modifications of these structures which are popularly known by the local titles of "meridian," "magnetic," or "compass" ants' nests. The termitaria belonging to this category are distinguished by their elongate, much compressed contour, comparable in the most evenly constructed examples to huge slabs of undressed sandstone set up on edge. The upper edge or ridge of the "Meridian" termitarium is always the narrower, and is either nearly smooth, irregularly serrated, or may be developed into a series of slender pinnacles. The most notable feature respecting these white ant mounds is, however, the circumstance that the orientation of their longer axis is always coincident with the local parallel of latitude, or, in other words, in a precise line with the north and south points of the magnetic compass.

The most striking examples of these meridian ants' nests observed by the writer occur in the Laura Valley, North Queensland, some sixty miles from Cooktown. The altitude of these Laura Valley ant mounds is not very considerable, rarely, indeed, exceeding six or eight feet. In accord with the peat-like alluvium out of which they are excavated and constructed, their colour is a dark ashen grey or nearly black. A distinctive feature of these meridian ants' nests is their highly ornate architectural style. They consist of a congeries of slender pinnacles erected close to one another in the same straight line, and which are finally amalgamated. Upon these primary pinnacles numerous subsidiary ones are usually constructed. The completed edifice, with its full complement of spires and pinnacles, comes thus when viewed end on, as shown in certain of the photographs taken, to present in miniature a by no means remote resemblance to the architectural pile of some grand cathedral.

A second and simpler form of meridian ants' nest is especially abundant a few miles inland from Port Darwin. It differs from the preceding type in its more massive and less ornate structural plan. The upper edge is nearly smooth or irregularly serrated, but not produced into a series of slender pinnacles. It is further noteworthy, that the environments pertaining to these two meridian varieties differ materially. With the Port Darwin type the habitat affected is that of open grassy plains, while in the Laura Valley form the nest mounds are most abundantly constructed in typical, though thinly wooded forest land.

The *raison d'être* of the north and south directions of the longer axial planes, so eminently characteristic of the so-called "Meridian" ants' nests, has given rise to much speculation and a variety of interpretations. By some it is supposed to bear a direct relationship to the prevailing winds. As, however, those in the districts where these ant-hills occur are chiefly south-east or north-west, according to the seasonal monsoon, that interpretation cannot be accepted as satisfactory. To the writer's mind a more probable explanation would appear to present itself in connection with the circumstance that being constructed in this precise meridian line, their larger surface presents the least possibly prolonged exposure to the meridianal rays of the tropical sun, and that the structures are consequently so built that they shall absorb and retain a minimum amount of solar heat. This question is, however, an interesting one that undoubtedly invites further scientific investigation. The subject of Australian termitaria constitutes, it may be noted, a copiously illustrated chapter in the writer's recently published work, "The Naturalist in Australia."

W. SAVILLE-KENT.

THE LIQUEFACTION OF FLUORINE.

FLUORINE was prepared for the first time in 1886 by Prof. Moissan, as a product of the electrolysis of anhydrous hydrogen fluoride contained in a platinum apparatus provided with fluorspar stoppers; the new gas was at once found to be the most active chemical substance known, many elements and organic compounds, such as arsenic, antimony, sulphur, iodine, alcohol, and turpentine, immediately and spontaneously bursting into flame when plunged into an atmosphere of fluorine. On mixing the gas with hydrogen, even in the dark, a violent detonation immediately occurs, hydrogen fluoride being produced. The violent action of fluorine upon nearly all substances with which it is brought into contact, obviously renders extremely difficult all experimental work involving the use of the free element. The great manipulative difficulties necessarily arising whilst dealing with the gas on the large scale have, however, been very happily surmounted by Prof. Moissan and Prof. Dewar, who recently described to the Chemical Society the method by which they have succeeded in liquefying fluorine, and determining the more important properties of the liquid substance (*Proc. Chem. Soc.*, November 4, 1897, p. 175). It seemed likely that the great chemical activity of fluorine might so far decrease at low temperatures as to allow of the manipulation of the material in a glass vessel cooled in liquid air; this was found to be the case.

The fluorine required in the work was prepared by the electrolysis of anhydrous hydrogen fluoride; this liquid being a non-conductor, was made a conductor by dissolving in it potassium fluoride. The liberated fluorine was freed from hydrogen fluoride by being passed first through a platinum worm immersed in a cooling mixture of solid carbon dioxide and alcohol, and subsequently through platinum tubes containing dry sodium fluoride. The purified gas was then passed down a vertical platinum tube fused to the neck of a thin glass bulb which served as the collector, and an exit was provided through a narrower platinum tube contained inside the first. On cooling the apparatus down to – 183° in boiling oxygen whilst the fluorine is passing through, no liquefaction occurs, but on reducing the pressure under which the oxygen is boiling, and so lowering the temperature to – 185°, the fluorine condenses in the glass bulb to a very mobile yellow liquid; on removing the bulb from the cooling bath the liquid fluorine boils vigorously. Other experiments made with boiling liquid oxygen and liquid air as refrigerating agents indicated that fluorine boils at about – 187°, namely at the boiling point of liquid argon; from this the probable critical temperature and pressure of fluorine are deduced as – 120° and 40 atmospheres respectively.

At these low temperatures fluorine is without action on glass, and does not displace iodine from iodides; silicon, boron, carbon, sulphur, phosphorus and reduced iron, all of which spontaneously ignite when brought into contact with fluorine at ordinary temperatures, do not inflame if, after being cooled in liquid oxygen, they are plunged into an atmosphere of fluorine. Hydrogen gas inflames spontaneously, with considerable evolution of light and heat, when directed on to the surface of liquid fluorine at – 190°; on passing fluorine on to solidified turpentine cooled by boiling liquid air, a series of explosions occurred resulting in the destruction of the apparatus. It thus seems that the great affinity existing between hydrogen and fluorine is not overcome at – 190°. A little liquid fluorine falling on the floor instantly inflames the wood. Fluorine is soluble in liquid oxygen, and on passing in the gas a white flocculent precipitate is formed which, after filtering off, deflagrates violently as the temperature rises; it is possibly a hydrate of fluorine.

Determinations made by floating pieces of various substances in liquid fluorine indicate that its density is about 1·14, and from the invisibility of amber immersed in the liquid the refractive index of the latter would seem to be higher than that of liquid air or oxygen. Liquid fluorine shows no magnetic phenomena when placed between the poles of a powerful electromagnet; it has a smaller capillarity constant than liquid oxygen, and does not solidify at – 210°. It has no absorption spectrum, and its colour is the same as that of the gaseous element.

W. J. P.

THE LEONID DISPLAY, 1897.

VERY unfavourable weather appears to have prevented the successful observation of the Leonids at their recent return. In consequence of this the impression seems to have gained ground that the phenomenon did not occur as predicted. This is, however, a mistake. Could those observers who saw so little on the night of the 13th, have viewed the sky late on the following night, they must have been satisfied at the character of the display. Between about 4.30 and 6 a.m. on Monday morning the 15th, the usual streak-leaving meteors from Leo became very numerous, and some of them were unusually brilliant, one, which appeared at 5.25 a.m., being brighter than the moon. Unfortunately the sky was overcast at the great majority of places at the time when the maximum occurred, and very few reports have come to hand, but they furnish unquestionable evidence as to a plentiful fall of meteors in the few hours preceding sunrise on the 15th.

Before midnight on the 13th, and during the early morning hours of the 14th, meteors were comparatively rare, and may be said to have been more conspicuous by their absence than by their presence. The shower of Leonids was of an extremely meagre character, and such as might occur in an ordinary year with the parent comet near its aphelion. But, apart from the disappointing meteors, the night of the 13th was one of singular beauty. At Bristol the sky partly cleared at 11.30 p.m., and the atmosphere became remarkably transparent. The moon and stars shone very brightly, and films of white cloud, floating rapidly across the sky, gave it a very picturesque appearance.

From the observations reported it may be well to make a few extracts:—

Mr. S. H. R. Salmon, South Croydon.—Sky perfectly clear November 13, 14h. to 16h. About seven meteors seen, including four bright ones as under:

h.	m.	s.	
15	3	45	First mag. from Andromeda.
15	28	0	First mag. Leonid.
15	32	45	First mag. Not a Leonid.
15	53	0	= Sirius. Probably a Leonid. It fell in a curved path slightly south of Jupiter, and was a beautiful object.

Rev. S. J. Johnson, Bridport.—Tolerably clear on November 13, between 15h. and 15h. 30m., but not a single meteor was observed.

Miss Brown, Cirencester.—The sky was perfectly clear on November 13, 11h. 45m. to 13h. 15m., and the eastern sky was watched from a window facing that quarter, but no meteors were seen.

Mr. W. H. Milligan, Belfast.—Cloudy weather prevented observation except on one night, November 13, 11h. to 12h. 30m., when only one sporadic meteor was recorded; no Leonids.

D. W. Walton, Kingston-on-Thames.—Sky clear and moon bright on November 13, 10h. 30m. to 11h. 30m., but only one meteor appeared. Partly overcast afterwards, but a few faint meteors were noticed in breaks between the clouds.

Bristol.—The writer watched the sky on November 13, between about 11h. 30m. and 13h., but no Leonids were recorded. The sky clouded after 14h., and the following night was overcast throughout. Mr. Corder, at Bridgwater, reports that the nights following November 13 and 14 were too cloudy to permit of observation.

W. Trueman Tucker, Loughborough.—On November 14 the clouds cleared away between 16h. and 16h. 30m., but the moon was very bright, and must have extinguished many of the smaller meteors. Between 16h. 30m. and 18h. a considerable number of shooting stars were observed, but no exact count was kept. The lines and approximate paths of ten of the more conspicuous ones were noted, and the brightest of all appeared in Cepheus at 17h. 25m. It was sufficiently luminous to cast distinct shadows in spite of the moonlight. Very brilliant meteors also fell at 17h. 10m., 17h. 15m., 17h. 35m. and 17h. 40m.

The Dumfries and Galloway Standard of November 17 reports that the nights of November 12 and 13 were overcast. On November 14, soon after midnight, the clouds began to roll off, and the sky afterwards became very clear. An amateur observer began watching at 12h. 30m., and from that time until 16h. 15m. he noted in all only thirty-three meteors, not more than thirteen or fourteen being Leonids. He then, thinking the outlook not sufficiently promising for any striking development of the shower, folded up his note book and star charts and retired. Shortly afterwards, however, the Leonids increased rapidly both in numbers and brilliancy. At about 16h. 50m. "a couple of young bakers going along the Whitesands to their work, were startled by many meteors throwing their fiery lances athwart the sky. They estimate the numbers as not fewer than ten shooting stars to the minute, and state they never saw so many before in all their lives."

The latter description is probably exaggerated, but it seems to convey an expression of fact such as we should expect from persons not acquainted with, but surprised by, an unusual celestial event. Though the rough estimate given as to the number of meteors visible may far exceed the actual figures, there is no doubt from the corroborative testimony afforded by Mr. Tucker at Loughborough, quoted in a previous paragraph, that the Leonid shower displayed quite a special activity on the morning of November 15. That it was apparently observed by few persons is unfortunate, but no other result could be expected in view of the cloud-laden atmosphere which prevailed, generally, at the time. It is to be hoped that more favourable conditions obtained at foreign stations, and that successful observations were secured. The shower seems to have presented itself somewhat later than the time expected, both in 1896 and 1897.

W. F. DENNING.

M. FORSTER HEDDLE, M.D.

EARLY on the morning of November 19 there passed away at St. Andrews the foremost mineralogist of Scotland, and one of the most distinguished in the United Kingdom.

Matthew Forster Heddle was the younger son of Robert Heddle, Esq., of Melsettar, in Orkney, and was born in 1828. In 1844 he went to the University of Edinburgh, where he studied medicine and attended the classes of Gregory and Jameson. Even at this time his tastes lay in the direction of science; and on the completion of his medical studies he proceeded to Germany, where he devoted himself to chemistry and mineralogy, at first in Clausthal and afterwards under the illustrious Breithaupt at Freiburg. Returning to Edinburgh, he took his degree as Doctor of Medicine in 1851, his graduation thesis being a treatise "On the Ores of the Metals."

He practised for a short time in Edinburgh, but never found this occupation a congenial one, devoting by degrees all his time to analysis and other scientific work. In 1856 he organised an expedition to the Faroe Islands. Five months of the summer of that year were spent in a mineralogical survey of the group, resulting in large additions to his cabinet, and putting on a firm foundation his knowledge of the mode of occurrence of the zeolites of the tertiary volcanoes.

On Dr. Heddle's return from this expedition he was appointed assistant to Prof. Connell at the University of St. Andrews, and on Connell's death, in 1862, he succeeded him as Professor of Chemistry, occupying this chair for twenty-two years. He threw himself with characteristic energy into his work at the University, spending a very considerable part of his salary in the purchase and fitting up of the apparatus for his experiments.

He found time, however, during these years for much mineralogical work, in the course of which he again and again traversed the whole North of Scotland and the Western Islands, thus acquiring an unrivalled acquaintance with its rocks and minerals. The results of these explorations were embodied in a series of papers, read principally before the Royal Society of Edinburgh, of which he was, in 1878, elected a Fellow, and the Mineralogical Society, of which he was one of the founders, and whose President he afterwards became. In addition to these and other papers of a geological and mineralogical nature, he undertook, in 1858, the revision and practically the editorship of Greg and Lettsom's "Mineralogy of Great Britain and Ireland," to which he made many original contributions. He also wrote the article "Mineralogy" for the last edition of the "Encyclopædia Britannica." In 1878 he received the Keith medal of the Royal Society of Edinburgh. Until a few weeks before his death he was engaged on an exhaustive work upon the mineralogy of Scotland, bringing together the results of all his investigations and analyses. This he left almost complete, and it is to be hoped that it may shortly be published.

In the long course of his mineralogical activity Dr. Heddle gathered very large and valuable collections of minerals, both general and Scottish. The latter of these, the fruit of many journeyings, was three years ago acquired by the Museum of Science and Art, Edinburgh, and is now on exhibition there, arranged and labelled by Dr. Heddle himself.

Although a specialist in mineralogy, Dr. Heddle's sympathies were not by any means confined to this subject, and embraced not only cognate sciences, such as chemistry on the one side and geology on the other, but extended to many other branches of science. As a chemist he was most painstaking and exact, and has published several hundreds of analyses of Scottish minerals, collected and carefully picked by himself. He was always most particular to indicate the possible impurities as a geologist. He published detailed maps of Shetland and Sutherland, and contributed to the unravelling of the problem of the North-west Highlands. He was a very observant student of the influence of geological structure upon the scenery of a country. In some respects he was in advance of his time as a geologist, and has lived to see suggestions, which were ignored when made by him, worked out by others and generally accepted. Many of his papers, which were founded on a wide research, are extremely suggestive and instructive. Perhaps among the best known are those where he expounds his law of pseudomorphous replacement, and where he enunciates the connection between the colloidal and crystalline states of a substance and its specific heat.

Dr. Heddle had an acute and exact eye, a clear intellect, and a wonderful memory. He was a good draughtsman, and his crystal drawings were most admirable. He grudged no trouble in smoothing the path of the tyro in his favourite science, and was most generous in his recognition of any work done by others. His kindly and genial disposition endeared him to a wide circle of friends.

J. C.

NOTES.

M. MOUREAUX has just completed the installation of the new magnetic department of the Parc St. Maur Observatory; and it will be set in operation on December 1. The work at the old magnetic rooms will be continued until January 1, in order to supply M. Moureaux with a sufficient number of observations for a reduction of the valuable records obtained continuously during a number of years.

PROF. JAMES B. HATCHER, curator of the department of vertebrate palæontology of Princeton University, sailed from New York a few days ago for Rio Janeiro, *en route* for Southern Patagonia. He expects to land finally at Punta Arenas, and thence work northward along the eastern base of the Andes as far as the Argentine territory of Chubut, studying the palæontology and geology of the country. The expedition will be gone three years, and aims to bring home a complete collection of birds and mammals from the Tertiary deposits of Patagonia.

IN the course of next month, the American Philosophical Society will award the Magellanic gold medal to the author of what is adjudged to be the best discovery, or most useful invention, relating to navigation, astronomy, or natural philosophy (mere natural history—the words are the Society's own—only excepted). The prize was founded in 1786 by John H. de Magellan, of London, and consists of a medal "of solid standard gold of the value of ten guineas."

SIR WILLIAM CROOKES will be the guest of the evening at the Club House Dinner of the Camera Club on December 7.

AT the meeting of the Entomological Society of London last week, the Chairman referred with regret to the death, while serving on the Indian Frontier Expedition, of Captain E. Y. Watson, Fellow of the Society, and well known for his writings on Oriental Rhopalocera.

THE Paris Academy of Medicine has been authorised to accept the legacy of forty thousand francs bequeathed to it by Dr. Eugène Dupierris. The legacy is to be used to found a biennial prize for the best work on anæsthesia, or on diseases of the urinary canals.

A NEW medical society has been formed in St. Petersburg: it will be known as the St. Petersburg Ophthalmological Society, and its first president is Prof. Dobrovolski.

THE *Athenæum* states that the first meeting of the present session of the German Chemical Society at Berlin was devoted to a *Gedächtnisfeier* in honour of the late Prof. Victor Meyer.

JUBILEE medals have been conferred upon Dr. Günther, President of the Linnean Society, Prof. Dewar, president of the Chemical Society; and Prof. R. Meldola, late president of the Entomological Society.

PROF. A. BAUER has been obliged, on account of ill-health, to decline the office of president of the third International Congress for Applied Chemistry, which is to be held next year at Vienna, and Dr. H. R. von Perger has been elected in his stead. There will be twelve sections in connection with the Congress. Among the subjects to be discussed is the introduction of uniform methods of analysis of chemical products.

THE Paris correspondent of the *Lancet* notes the return of M. Raoul from Malaita, where he has for some time been engaged for the Government in making researches as to the existence of indigenous plants that might be turned to account scientifically or commercially. Several members of M. Raoul's party were bitten by snakes of different kinds, and were injected with Dr. Calmette's serum with very great success.

DR. A. LUSTIG, writing in the *Atti dei Lincei*, describes some important observations made in India on vaccination as a preventive of bubonic plague, and also on sero-therapic methods of treatment. At the time when the plague was raging in Bombay last June, Dr. Lustig made a number of experiments both on human subjects and on monkeys. Thirty persons suffering from the disease were inoculated with serum, and of these only four died during the treatment. In conjunction with Dr. G. Galeotti, the same writer made experiments on rats with a view of ascertaining whether there existed any hereditary transmission of the immunity conferred by vaccination. It was found that in no case did vaccination of either or both parent animals at any stage prevent the progeny from taking the disease.

IN the Budget of the French Minister of the Interior, the grant of 106,000 francs for the therapeutic serum service of the

Pasteur Institute is set down for payment. In 1895, 45,203 doses of anti-diphtheric serum, each ten centigrams in amount, were distributed gratuitously, and in 1896 the number was 28,217. Since the commencement of the work, as many as 137,058 doses of antitoxic serum have been distributed by the Institute, 5500 of them being for veterinary purposes.

WE regret to announce the death of Dr. F. Stohmann, honorary professor of agricultural chemistry in the University of Leipzig; and also of Dr. J. Frenzel, curator of the "Müggelsee" biological station near Berlin, and formerly professor of zoology in the Cordoba University, Argentine Republic.

THE death of Dr. Leonhard Sohncke, at the age of fifty-five, is announced. Dr. Sohncke at the time of his death was professor of experimental physics and director of the Physical Laboratory at the Munich Technical High School.

THE Natural History Society of Hanover will celebrate its centenary on December 10-12.

IN a previous number of NATURE (vol. lvii. p. 32) we referred to the death of Prof. Ernst Schering, of Göttingen. Some interesting details of his life and work have now been published by Prof. Wilhelm Schur (*Astronomische Nachrichten*, No. 3458), to which brief reference may be made. Born in the year 1833 at Sandbergen, near Lüneburg, Schering studied in Göttingen under Gauss from the year 1852, was made "ausserordentlicher" professor in 1860, and "ordentlicher" in 1868. In 1869 the magnetic part of the observatory department was made distinct from the astronomical, and the former put under the direction of Schering with the object of continuing the magnetic observations made in the first instance by Gauss. After Klinkerfues' death Schering took over the direction of both departments. During the years 1858 to 1863 Schering took part with Klinkerfues in the zone-observations, which were published in 1891. In 1874 he published a generalisation of Poisson-Jacobi's perturbation formulæ, in 1877 a "Festrede" at the celebration of the hundredth anniversary of Gauss's birthday, and in 1884 a solution of Kepler's equation (*Astronomische Nachrichten*, 2605). His chief work was, however, the publication of Gauss's works in seven volumes. Schering leaves behind him, besides a widow, one daughter and two sons.

Science states that the American Society of Naturalists and the affiliated societies will meet at Ithaca, N.Y., on December 28, 29 and 30. At the opening meeting an address of welcome will be delivered by President Schurman. On the second day of the meeting the principal item on the programme is a discussion on "The Biological Problems of To-day," in which the following speakers will take part: Prof. H. F. Osborn (on Palæontology), Prof. W. Trelease (on Botany), Prof. B. G. Wilder (on Anatomy), Prof. McKeen Cattell (on Psychology), Prof. J. Loeb (on Physiology), Prof. T. H. Morgan (on Developmental Mechanics), Prof. C. B. Davenport (on Morphogenesis).

PROF. TH. W. ENGELMANN, of Utrecht, has just published (Wilhelm Engelmann, Leipzig) a small case (6¼ × 9⅛ inches) containing two sets of tables on which it is intended the results of spectroscopic and spectrophotometric observations may be plotted. The first table, of which there are nine duplicates, consists of six coloured continuous spectra arranged under one another, which serve as a background, so to speak, on which absorption spectra may be drawn. A series of vertical lines forms the scale of wave-lengths, and the positions of the chief Fraunhofer lines are marked in the upper strip. The second table, of which there are also nine similar ones, is somewhat differently arranged. At the upper part is a coloured continuous spectrum as before, with the positions of the chief Fraunhofer lines marked, and below is a series of horizontal and vertical lines, the former to represent the wave-lengths, and the latter the intensities per cent. This will be found useful for recording the positions and extensions of absorption-bands, and determining the light-curve of the spectra under investigation. Both these sets of tables are impressed on good thick sheets of paper, and the coloured spectra and graduations are very neatly reproduced. It is a pity that the red end of the spectrum is placed on the left, and not on the right hand, as this may tend considerably to diminish the usefulness of these cards. Accompanying these sheets are also two numerical tables expressing (1) the coefficients of extinction for different intensities, and (2) the relative intensities after the passage through coloured media of different thicknesses.

THE *Proceedings* of the Liverpool Geological Society for the last session contains a paper by the president, Mr. J. Lomas, on the Hereford earthquake of last December. The map which accompanies it shows the isoseismal lines, so far as they can be drawn, corresponding to the intensities 4, 5, 6 and 7 of the Rossi-Forel scale. These curves are somewhat elliptical in shape, and are grouped symmetrically about a line running N.N.W. from a point a little east of Hereford. Mr. Lomas attributes the earthquake to the friction generated by the slipping of strata somewhere along the Severn Valley, and he considers it probable that the slip extended for some distance along the axis of the isoseismals.

THE effect of temperatures upon the hibernation of injurious insects forms the subject of a short paper by Dr. L. O. Howard in the *Proceedings* of the ninth annual meeting of the Association of Economic Entomologists, just issued by the U.S. Department of Agriculture. It is a well-known fact among agriculturists and horticulturists that winter weather of a steady degree of severity is more favourable to plant growth than a winter with alternating frosts and thaws. With regard to certain injurious insects, it has become an accepted idea among economic entomologists that this same principle holds good, but farmers and others believe a winter which has been unusually severe will result in the destruction of injurious insects to such an extent as to promise comparative immunity in the next season. Experiments were required to throw light upon the matter, and these have been carried out by Dr. Albert M. Read, of Washington, the manager of the cold storage department of the American Security and Trust Company. Dr. Read has found, in the course of his experiments, that a consistent temperature in the neighbourhood of 18° F. will not destroy the larvæ of *Tineola biscelliella* or of *Attagenus piceus*, but that an alternation of a low temperature with a comparatively high one invariably results in the death of the larvæ of these two insects. For example, if larvæ of either which have been kept at a temperature of 18° F. are removed to a temperature of from 40° to 50° F. they will become slightly active, and when returned to the lower temperature and kept there for a little time, will not revive upon a retransfer to the warmer temperature. Dr. Howard remarks that it is satisfactory to have experimental proof in support of previously accepted, but more or less theoretical, ideas.

AT the Imperial Institute on Monday night, Mr. E. S. Bruce gave a lecture on his system of electric balloon signalling as applied to scientific exploration in Arctic and Antarctic regions. Major P. A. MacMahon was in the chair. After pointing out how great an advantage it would be for a party to have a means of communicating with the ship when away on an exploring expedition, the lecturer described his system, in which a group of electric lamps was mounted inside a balloon connected with the earth by an electric cable. The operator and most of the apparatus would be on the ground or the deck of a ship, and therefore the balloon could be made easily portable. Goldbeaters' skin would be the best material to employ for the covering, and the smallest size of balloon he could recommend for Arctic exploration purposes would be about 7 feet in diameter, with a capacity of 150 cubic feet and able to lift 500 feet of cable. The necessary gas could be stored in steel tubes, or a portable gas-making machine might be carried. The source of electric power would be a dynamo, with which Mr. Bruce supposed every future Arctic expedition would be provided, and this could be operated by wind power, if coal ran short, or even by hand. By giving long and short flashes on the lamps, it would be possible to convey messages in the Morse alphabet.

SOME time ago, G. Jung gave a solution of the problem "to determine by the method of least squares the plane which most nearly coincides with *n* non-coplanar points." In the *Rendiconti del R. Istituto Lombardo*, ii. xxx. 16, a brief abstract is given of an investigation by the same writer of the reciprocal problem: "Given *n* non-concurrent planes, to find the point most nearly determined by them." The corresponding problem in plane geometry has been attacked by M. d'Ocagne, and Prof. Jung has thus extended the method to three-dimension space, besides giving a generalisation of certain constructions first investigated by M. Berthot.

IN the *Journal of the Royal Statistical Society* (September), Mr. W. F. Sheppard considers the calculation of the average square, cube, &c., of a large number of magnitudes. Supposing that a number of measurements are tabulated to the nearest multiple of a particular unit (*e.g.* the chest measurements of 5732 Scotch soldiers to the nearest *inch*), the data do not enable us to find *exactly* the true average measurement or the average square or cube of the magnitudes. Mr. Sheppard shows that the *rough value*, obtained by supposing each measurement to be equal to the nearest multiple of the unit, differs in some cases considerably from the *most probable* value of the average in question, and he finds that for laws of distribution which satisfy certain conditions a very close approximation to the latter may be obtained by applying certain simple corrections to the "rough values" first calculated.

IN the *Mathematical Gazette* for October we are glad to see that Mr. R. F. Muirhead calls attention to the old treatment of the "Parallelograms of Velocities and Accelerations," which still survives in many otherwise excellent text-books on dynamics. The enunciation often introduces the notion of "a moving point or body possessing simultaneously two velocities," a notion which is meaningless until coexistent velocities (which would better be spoken of as "velocity components") have been defined. The usual (so-called) "proof" tacitly involves the idea of a body *moving relatively* to a certain base which is itself in motion, but as the word "relative" is generally omitted, and the parallelogram of velocities is usually given before relative motion is considered, and, moreover, is employed in the discussion of relative motion, the learner's mind is often puzzled and he fails to grasp the theorem. Mr. Muirhead rightly contends that the only logical way out of the difficulty is to make relative motion precede the discussion of the parallelogram law, unless, indeed, the latter be regarded merely as a *definition* of component velocities and acceleration.

WE have received from Mr. R. C. Mossman a copy of a very valuable and laborious investigation of the Meteorology of Edinburgh, based upon observations during the past 132 years, from documents mainly collected by the Scottish Meteorological Society. The work is published in the *Transactions* of the Royal Society of Edinburgh, and is divided into two parts, the first dealing with the climatic elements for each day of the year, and the second with monthly and annual means, and with secular and other weather changes. The smoothed curves show that the warmest day of the year falls on July 15, and the coldest on January 8. The mean daily maximum temperature is above the annual average (46°·8) from April 26 to October 14, but the mean minimum does not get above the yearly mean until May 12, and it remains above it till October 19. The greatest excess of sun over shade temperature was 76°·8 in March 1892, and the grass minimum thermometer fell 12°·6 below the minimum in shade in May 1890. The mean annual rainfall is 25·86 inches; the wettest period is that embraced in the seven days ending August 18; while the period distinguished by the least rain-fall, is the week ending with March 27. One very interesting feature of the discussion is a chronological appendix of remarkable atmospheric phenomena at Edinburgh, extending from 1575 to 1895, which has been compiled from a variety of sources.

A NOTE in *Science* states that Dr. O. Holst, of the Geological Survey of Sweden, after two years' leave of absence granted him for the purpose of studying the new gold-fields in Western Australia, has now returned. Dr. Holst saw the ancient Australian glacial deposit which is supposed to belong to the Permian age, and says there can be no doubt but that it is an indurated boulder-clay. Its age may possibly be somewhat later than heretofore supposed, but not so much later as to detract from the importance of its bearing on the subject of geological climate. In the semi-desert, where Dr. Holst spent most of his time, the wind did not appear to him to be of any great importance as a geological agent, although dust storms are sometimes reported from the new towns on the border of the desert. One of the Australian geologists has lately made some interesting observations on what resembles a tidal action of the ground water in the sandy region in the interior. The water rises and falls at regular daily intervals, and the oscillations appear to be too great to be explained as resulting from the daily variations in atmospheric pressure.

THE *Electrician* calls attention to a new development in the design of electrically-propelled pleasure craft, which has been given the name of the "Nymph." Briefly, the "Nymph" is an attachment to an ordinary pleasure boat, sailing ahead of it but rigidly connected to it, the boat containing the accumulator cells and the switch-gear by which is controlled the motor in the body of the swan-shaped tug. The craft is guided or steered by two reins attached to the head of the "swan," and these reins actuate by gear the ordinary rudder. A regulator situated close to the right-hand of the driver enables him to control the speed of the motor and propeller in the "swan," and to go at full or half-speed, ahead or astern. There are sixteen chloride cells of seventeen plates each, and these, for starting and low speeds, are connected to the motor in two parallels of eight cells each, all the cells being used in series for full speed. The total electrical capacity of the battery is about 300 ampere hours, and this is equal to propelling the boat at a speed of eight miles an hour for six hours, or a total distance of about fifty miles, with six people on board. No resistances are used, and neither the field nor the armature is divided up in any way to regulate the speed. The vibration of the boat is perceptibly less than in one containing the motor. Although the arrangement lends itself to graceful design, there is probably considerable loss of efficiency as compared with the usual stern propeller.

THE Commission appointed by the German Government to study the plague in Bombay, and which commenced its work under the presidency of Prof. Dr. Gaffky last March, has published the results of its labours in several numbers of the *Deutsche medicinische Wochenschrift*. The report is a very elaborate and exhaustive one, and contains a mass of valuable experimental material. It would appear that in the majority of cases the plague-bacillus obtains access to its victims through small wounds or scratches on the body, reminding one of the same method adopted by the anthrax bacillus for infection. As Yersin has already pointed out, plague is essentially a disease which afflicts the poor and miserably-housed lower classes of the population, their habits and repugnance to all sanitary precautions, and prejudice against the hospitals, rendering its suppression a matter of extreme difficulty. In the hospitals, thanks to systematic disinfection and scrupulous cleanliness, cases of plague amongst the staff were very rare. The Commission have discovered that the serum of human beings, as well as that of animals which have recovered from plague, exerts a specific action on plague bacilli outside the body, producing the phenomenon of the clumping together of the bacilli now so familiar in the case of typhoid bacilli under similar circumstances. Numerous researches were carried out to test the vitality and powers of endurance possessed by these bacilli under very varied conditions. For example, in sterilised tap-water they were found to be dead after three days, whilst in ordinary tap-water a single day's immersion was sufficient to destroy them. Very sensitive also are these microbes to the action of disinfectants, corrosive sublimate diluted to 1 in 1000 parts at once destroys them, whilst a 1 per cent. solution of carbolic acid also kills them within ten minutes. Heating for ten minutes at 55° C. destroys them, as also does exposure to a temperature of 80° C. for five minutes, whilst in a liquid just brought to the boiling point, and at once examined, they were also entirely annihilated. Perhaps the most interesting part of the report is that which deals with the inquiries made into the respective merits of Yersin's and Haffkine's anti-plague inoculations. Yersin's serum inoculations in Bombay do not appear to have been as successful as those which he previously carried out in cases of plague at Amoy. Dr. Roux was, however, preparing a yet stronger serum at the Paris Pasteur Institute, and it was hoped that it might prove more efficacious. On the other hand, Haffkine's inoculations appear to have been very successful, although the protection against plague afforded by them is by no means absolute. Haffkine's method consists in adding a weak solution of carbolic acid or essence of mustard to a virulent growth of plague bacilli, thereby destroying the microbes; their products, however, which remain, possess a remarkable protective power. The vaccine may also be procured by heating the plague-cultures to 65° C. for one hour, or during two hours to 51° C. This method of heating appears to yield the best vaccine. It is impossible here to enter into further details of this valuable report, which forms a most important contribution to the scientific literature already existing on plague and its dissemination.

MR. CHARLES LOUIS HETT, of Springfield, Brigg, has prepared a list of the calls of some two hundred British birds, and appeals for the assistance of other students of bird-life, either in checking calls already recorded, or in supplying those of other birds. He promises to finish the compilation and to issue it from the press, provided he receives the co-operation needed.

HERREN MAYER AND MÜLLER, of Berlin, ask for subscriptions for an important work on Orchids, of which the first volume is already in type—"Orchidacearum Genera et Species," by Prof. F. Kraenzlin, to be completed in six volumes. No complete separate systematic work on the Orchidaceæ has been published since Lindley's Synopsis, which was issued sixty years ago.

COHN'S "Kryptogamen-Flora von Schlesien" is a work of much more than local interest, the various families of Cryptogams having been worked out with the greatest care by experts in the various departments. The last part received (3er Band, 2te Hälfte, 4te Lieferung) completes the Pyrenomycetes, and contains an introduction to the so-called "Fungi imperfecti," those in which the conidial, but not the ascogenous form is known. This portion of the work will, unfortunately, remain uncompleted, as it stood in the hands of Dr. J. Schröter at the time of his death in 1894, Prof. Cohn not having been able to find any one to complete the work left unfinished by that eminent mycologist. An interesting feature of Dr. Schröter's work in this section of Fungi is that he has discarded the term genus, arranging the species under *Formgattungen* or "form-genera."

MESSRS. ROSS, LTD., have just issued a very full illustrated catalogue of the instruments made by them.

MESSRS. ABBOTT, JONES, AND CO. announce for early publication "The Life of James Abernethy, past-president of the Institute of Civil Engineers." The book will be the work of John S. Abernethy, and will be illustrated.

THE sixteenth Annual Report of the Bureau of American Ethnology has reached us, and contains the following papers:—"Primitive Trephining in Peru," "Cliff-Ruins of Canyon de Chelly, Arizona," "Day Symbols of the Maya Year," and "Tusayan Snake Ceremonies."

THE catalogues issued from time to time by Mr. Bernard Quaritch are always interesting, but few, if any, of those recently issued can compare with the one dated November 12, which has just reached us. It is entitled "Monuments of Printing," and contains particulars of books produced by the earliest presses in Germany, the Netherlands, Italy, France, Spain and England from 1455 to 1500, and a few remarkable examples of a somewhat later date. The catalogue is one which will be prized by all students of typography.

THE *Photogram* for November contains several short articles of interest to photographers. Mr. C. F. Townsend writes about sensitometers, giving a brief historical summary of the methods employed. Under the heading of "Applied Photography in Ship Salvage Work" is the title of an article by Mr. Charles H. Evans, who points out the many difficulties that are met with in this class of work. The illustrations accompanying the text are very much to the point, being good examples of the work undertaken. Other branches of the art dealt with are photomicrography, exact measurements with the X-rays, toning bromide prints, &c., together with useful information in the form of notes on many other points of interest.

VOLUME V. of the *Transactions* of the Institution of Mining and Metallurgy for the sixth session has reached us, and is a bulky work, containing reports of some eighteen papers, and the discussions which took place upon them. The Institution during the session referred to had upon its books the names of 449 members, associates and students, as against 372 for the session of 1895-96.

MESSRS. MACMILLAN will publish shortly a work entitled "A Text-Book of Zoology," under the joint authorship of Profs. T. Jeffery Parker and W. A. Haswell. Special attention is called to the illustrations, of which there are over a thousand in the two volumes that comprise the work. For the most part these illustrations are original, and have been drawn by Mr. N. J. Parker.

OF all the periodicals which come before us week by week, and month by month, not one fulfils its particular purpose better than the *Engineering Magazine*. The magazine is always attractively illustrated; the articles in it deal with subjects which are of prime importance in the engineering world; and the monthly digest of the entire technical press is a very valuable index to current technical literature. The issue of a distinctly European edition of the magazine was commenced last month, and we are confident that it will meet with as much success here as it has in the United States.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. F. Greswolde-Williams; a Suakin Gazelle (*Gazella brookii*) from Abyssinia, presented by Dr. L. de Gebert; two Ring-necked Parrakeets (*Palæornis torquatus*) from India, presented by Mrs. G. F. Cooper; a Macaque Monkey (*Macacus cynomolgus, albino*) from Manilla, presented by Mr. James Coombs; two Double-spurred Francolins (*Francolinus bicalcaratus*) from West Africa, four Rosy Bullfinches (*Erythrospiza githaginea*), bred in England, presented by Mr. E. G. B. Meade-Waldo; two Herring Gulls (*Larus argentatus*), British, presented by Mr. T. Hope Robinson; two Rhomb-marked Snakes (*Trimerorhinus rhombeatus*), two —— Snakes (*Chlorophis hoplogaster*), a Puff Adder (*Bitis arietans*) from South Africa, presented by Mr. J. E. Matcham; a Ring-tailed Lemur (*Lemur catta*, ♀) from Madagascar, a Macaque Monkey (*Macacus cynomolgus*) from India, deposited; six Rosy-faced Love Birds (*Agapornis roseicollis*) from South Africa, a Malaccan Parrakeet (*Palæornis longicauda*) from Malacca, four Siskins (*Chrysomitris spinus*), four Lesser Redpolls (*Linota rufescens*), British, a Bridled Wallaby (*Onychogale frenata*) from Australia, a Loggerhead Turtle (*Thalassochelys caretta*) from the Mediterranean, purchased.

OUR ASTRONOMICAL COLUMN.

THE NOVEMBER METEOR SWARMS.—Up to the present time we have not received any news that the Leonids were more abundant this year than last. Indeed, bad weather seems to have universally prevailed about the time of observation. At the Paris Observatory five observers only noted twenty meteors, while M. Hansky, at the Meudon Observatory, saw in all seven, four of which were Leonids. M. Janssen, in consequence of the exceedingly bad weather experienced in Western Europe, telegraphed to San Francisco to inquire whether a more brilliant display had been noted there. The answer he received was to the effect that nothing more than the ordinary shower was observed. Perhaps, however, observers may be (or may have been) more fortunate with the Andromedes, which are expected between the 23rd and 27th of this month. This swarm is also of considerable strength, and should be more than usually active. Its period of revolution being six and a half years, and the last maximum having occurred on November 23, 1892, we expect the shower this month to be above the ordinary yearly display. There are several points about the Andromedes that are of peculiar interest. One of these is that the orbit in which they move is very similar to that of the comet Biela; in fact, the bodies which produce the phenomena of shooting stars may be none other than the component parts of this comet. In the years 1872 and 1885 the maximum display occurred on the 27th of the month, but at the following expected shower it took place on the 23rd. This difference is explained, according to Bredichin, by the perturbatory effects due to the proximity of the planet Jupiter, thus causing the node to recede 4°. The radiant point of this swarm (25° + 43°) has a large northern declination, which renders it always above the horizon. The meteors themselves are different from the Leonids in that they move more slowly, and are of a yellowish tinge.

In the note under this heading, that appeared last week, it should have been mentioned that the observations recorded were made by Dr. W. J. S. Lockyer at the Solar Physics Observatory, South Kensington.

In another part of this journal Mr. Denning summarises the results of this year's Leonid display.

CURRENT ASTRONOMICAL ARTICLES.—M. Gaston Armelin contributes an interesting article on that curious variable Mira Ceti to *La Nature* for November (No. 1274). After a brief historical summary the writer describes some theories current to-day, and points out the variations in the time of maxima observed of late years, and their consequent suggested explanations.—The bulletin of the *Société Astronomique de France* for the same month contains, among other interesting matter, a drawing of comet Perrine as observed at the observatory of Juvisy. M. Camille Flammarion deals with the Leonid swarm of meteors. The number contains several contributions of planetary notes.—In the October number of *Himmel und Erde*, a brief account is given of the present state of the proposed large Potsdam refractor. There seems to have been some difficulty about the optical parts, so that it has been decided to assume that the aperture will be 80 cm., and commence at once with the construction of the instrument and a suitable dome. This instrument when finished will be then the largest in Europe, the aperture being nearly thirty-two inches. This article contains the results of many investigations on the absorption properties of different thicknesses and kinds of glass.

COMET PERRINE (OCTOBER 16).—This comet is gradually becoming fainter, but a continuation of the ephemeris for the current week will perhaps prove useful:—

REV. DR. SEARLE has resigned the directorship of the astronomical observatory of the Catholic University of America. His place will be taken by Mr. Alfred Doolittle.

THEORY OF THE MOTION OF THE MOON.[1]

OF the lunar theories hitherto completed the two greatest are undoubtedly those of Hansen and Delaunay. The former has for its chief object the formation of tables: the inconvenience of slowly converging series is avoided by using numerical values throughout; and the problem solved is the one actually presented by nature, every known cause of disturbance being allowed for. It suffers, however, under the disadvantage that there are no means of correcting the results for any change in the values of the constants that observation may demand. This drawback was avoided by Delaunay, but only at the expense of still greater evils from the point of view of the making of an ephemeris; for owing to the slow convergence of certain series, twenty years' labour did not suffice to give sufficiently approximate results; moreover, the problem had to be considerably modified from the circumstances of nature, in order to achieve a result within even so long a time.

The memoir that Dr. Brown has lately presented to the Royal Astronomical Society, forms the first part of a fresh attempt to calculate the motion of our satellite. All Delaunay's modifications of the problem are adopted: that is to say, the sun and earth are supposed centrobaric, the mass of the moon is neglected, as is also the action of the planets, and the true mass of the sun is increased by that of the earth. The calculation of the effect of the attraction of the planets and of the protuberant parts of the earth's equator will follow when the modified problem is solved. The solution can also be easily modified so as to allow for the greater part of the effect of the remaining modifications, and the outstanding error Dr. Brown has shown to be insensible to observation; but it is, however, far larger than the minute fraction of a second to which his calculations are pushed.

Dr. Brown's theory resembles Delaunay's in being algebraical with, however, one important exception: the ratio of the mean motions is replaced by its numerical value. By this means the slowly converging series that occur in Delaunay's theory are avoided; and no admissible correction of the value of the above ratio can introduce any change in the results that would be sensible to observation. This modification in the form, combined with the use of a totally different method of calculation will, Dr. Brown estimates, cut down the twenty years occupied by Delaunay over the same problem to five.

---

[1] "Theory of the Motion of the Moon." Containing a new calculation of the expressions for the coordinates of the Moon in terms of the time." By Ernest W. Brown, M.A., Sc.D. (Reprinted from the *Memoirs* of the Royal Astronomical Society, vol. liii.)

One great advantage of an algebraical theory is the facility with which the work can be divided into sections, each consisting in the calculation of a group of terms multiplied by the same power of the eccentricities, inclination, and solar parallax, or, in the language of the lunar theory, having the same characteristic. Delaunay's theory unfortunately lost this advantage by its peculiar methods, and substituted another form of subdivision that enormously increased the total labour in the desire to present each step in a moderate compass. Adams appears to have been the first to clearly recognise the advantages of a subdivision such as Dr. Brown has employed, but it was Dr. Hill who actually laid the foundations of the present theory. In the first volume of the *American Journal* he published his famous "Researches in the Lunar Theory," where, after the lapse of more than a century, he revived Euler's idea of using rectangular coordinates. Confining his investigations to the case when the eccentricities, inclination, and solar parallax are supposed to vanish, he used axes rotating so that the axis of x points constantly to the sun, and then replaced x, y by the conjugate complex variables $u, s = x \pm y\sqrt{-1}$, and the time by another complex quantity $\zeta = e^{(n-n')t\sqrt{-1}}$, and the symbol of differentiation by D defined as $\zeta\frac{d}{d\zeta}$. He also used the symbol m to denote the ratio of the synodic month to the sidereal year, and k to denote the mass of the earth divided by the square of the difference of the mean motions of the moon and the sun. He then arrived at the differential equations,

$$(\mathrm{D}+m)^2u + \tfrac{1}{2}m^2u + \tfrac{3}{2}m^2s - \frac{ku}{(us)^{\frac{3}{2}}} = 0$$

$$(\mathrm{D}-m)^2s + \tfrac{1}{2}m^2s + \tfrac{3}{2}m^2u - \frac{\kappa s}{(us)^{\frac{3}{2}}} = 0.$$

At this point arose a difficulty which, in a closely analogous form, is common to all lunar theories, the presence, that is to say, of the quantity denoting the mass of the earth divided by the cube of the distance. The practical convenience of a theory is perhaps in no way better tested than by examining the manner in which this difficulty is overcome, and it is certainly not too much to say that in this respect Dr. Hill's method has no rival. In a few brief steps he succeeds in eliminating the obnoxious quantity altogether, and he obtains two equations of the second degree in u, s and homogeneous in these variables except for a constant of integration, which may be looked upon as replacing k. These equations are easily solved numerically, and denoting the values of the variables with Dr. Hill's modifications of the general problem by the suffix zero, u_0 and its conjugate complex s_0 may be henceforth looked upon as known functions of the time. They are, in fact, capable of expression as infinite series of positive and negative odd powers of ζ. The coefficient of ζ in u_0 is denoted by a, which is a constant defining the linear dimensions of the orbit. By having recourse to one of the original equations containing k, the value of k/a^3, which is a mere number, may be found. This completes the investigation of the variation, as this class of inequalities is called.

It is at this point that Dr. Brown took up the subject. He replaced Dr. Hill's first pair of equations by the following set of three, the third of which determines z or the moon's coordinate perpendicular to the ecliptic, which in the particular case treated by Dr. Hill is zero

$$(\mathrm{D}+m)^2u + \tfrac{1}{2}m^2u + \tfrac{3}{2}m^2s - \frac{ku}{(us+z^2)^{\frac{3}{2}}} = -\frac{\partial\Omega_1}{\partial s}$$

$$(\mathrm{D}-m)^2s + \tfrac{1}{2}m^2s + \tfrac{3}{2}m^2u - \frac{ks}{(us+z^2)^{\frac{3}{2}}} = -\frac{\partial\Omega_1}{\partial u}$$

$$(\mathrm{D}^2-m^2)z - \frac{kz}{(us+z^2)^{\frac{3}{2}}} = -\tfrac{1}{2}\frac{\partial\Omega_1}{\partial z}.$$

In these equations Ω_1 represents the part of the disturbing function neglected by Dr. Hill, every term of which is divisible by either the solar eccentricity or parallax. The quantity k can be eliminated from the first two of these equations in a manner analogous to the methods of Dr. Hill. It can be also eliminated from the third and either of the other two in an obvious manner. The resulting equations need not be written down here; following Dr. Brown, they will be alluded to as the homogeneous equations. There are thus two distinct sets of equations that can be used at any step in the work. In practice one set is used, and a single equation from the other set is used in addition, generally as a mere equation of verification, but in certain special cases for the actual solution when the equations of the first set are not well adapted for the purpose. Dr. Brown's procedure is as follows: let

$$u = u_0 + u_\mu + u_\lambda \qquad z = z_\mu + z_\lambda$$

Where u_μ, s_μ denote the terms already calculated, u_λ, z_λ the new terms of characteristic λ to be calculated in the next step of the process of solution. Either u_λ or z_λ is always zero according as λ contains an odd or even power of the inclination. These values are then substituted in either set of differential equations, and the terms of order λ picked out. It can be readily seen that the right-hand side of the equations contain only known terms, and the unknown new terms occur in the first degree and multiplied by functions of $u_0\ s_0$ only. If the first set of equations be used, the terms containing k/r^3 must be expanded by Taylor's Theorem into series proceeding according to powers of $u_\mu + u_\lambda$, $s_\mu + s_\lambda$, $z_\mu + z_\lambda$ with coefficients containing k, u_0, s_0 only. These coefficients are easily deducible from Dr. Hill's value of u_0, the method of special values being in general used. One remark, however, requires to be made. Every time a set of terms is calculated whose arguments are the same as the terms in u_0, there arises the opportunity of modifying the meaning of the linear constant a. It is otherwise evident that any solution remains a solution when a is replaced by a new constant a' defined by the relation $a/a' - 1 =$ an arbitrary series of powers and products of the squares of the eccentricities, inclination, and solar parallax. The value of k is of course simultaneously modified also. Consequently we should be liable to have the values of such quantities as k/r_0^3 varying from time to time as the approximation proceeds. This would be obviously inconvenient, and Dr. Brown has used the power of modification at his disposal so that k/a^3 remains invariable throughout the solution, and therefore, since in Dr. Hill's papers it is a function of m only, it always remains so.

In the first set of equations therefore the unknown terms enter in the form

$$\zeta^{-1}(\mathrm{D}+m)^2u_\lambda + \mathrm{M}\zeta^{-1}u_\lambda + \mathrm{N}\zeta s_\lambda$$

and

$$\mathrm{D}^2z_\lambda - 2\mathrm{M}z_\lambda$$

where

$$\mathrm{M} = \tfrac{1}{2}m^2 + \tfrac{1}{2}\frac{k}{\rho_0^{\,3}}$$

$$\mathrm{N} = \tfrac{3}{2}m^2\zeta^{-2} + \tfrac{3}{2}\frac{ku_0^{\,2}\zeta^{-2}}{\rho_0^{\,5}}$$

the same form at every approximation. (A misprint in the algebraical value of N, on p. 63, should be noticed; the factor ζ^{-2} being there omitted. This is merely a printer's error, for the arithmetical value on p. 90 is correctly given. Indeed, were it otherwise, the discordance of the results from those of other theories would long ago have been noticed.)

When the new terms to be calculated have the same arguments as u_e or z_k, the principal elliptic or inclinational terms, a new term in the motion of the perigee or node (of order λ/e or λ/k) has to be calculated. The unknown term $c_{\lambda/e}$ appears multiplied by $2(\mathrm{D}+m)u_e$ in the first equation, and $g_{\lambda/k}$ appears multiplied by $2\mathrm{D}z_k$ in the second equation. These coefficients are independent of λ: since, however, λ must be of at least the third order for the point to arise, it does not properly enter into the part of the work already published.

A series with indeterminate coefficients is then assumed for u_λ or z_λ: and a number of simultaneous equations formed, from which the coefficients are found. The labour of forming the known terms in these equations increases rapidly with the characteristic; but the operations required are mere multiplication of series, and can to a great extent be left to a computer. The results are readily checked by computing independently the value when $\zeta = 1$.

The unknown terms enter at each step into the equations under the same algebraical form, or rather under one of two forms, according as the new terms belong to u or z. These forms unfortunately involve the symbol of differentiation D, so that the different sets of simultaneous equations have different arithmetical coefficients; but whenever more terms with an old set of arguments are being calculated, the arithmetical coefficients are the same as before, and it is only the right-hand sides which are different. This greatly facilitates the labour of solution; but the advantage is obviously one that is deferred to the later stages of the work, the only instances in the part of the work hitherto published being that the calculations of sections (v.) and (viii.) of chapter iv. are to some extent facilitated by the previous calculation of section (ii.) of the same chapter.

The ordinary method of approximation in the simultaneous equations proceeds by determining approximate values of the unknown quantities in order of magnitude, at first neglecting the smaller of these quantities in the equations of principal importance for determining the larger ones. It happens, from a well-known cause, that sometimes the coefficients of certain unknowns are small even in the equations of principal importance in determining them. Prof. Brown has, in these cases, found it best to defer their determination until he has found all the other quantities in terms of them.

After considerable experience of both sets of differential equations, Prof. Brown has come to the conclusion that the first set on the whole is the best adapted to the numerical work. An important exception, however, arises. The two coefficients of a term of long period are principally determined by two equations very nearly deducible, the one from the other, the determinant of the coefficient varying inversely as the square of the period. The difficulty is considerably lessened by using one equation derived from the homogeneous set.

The following table will give some idea of the extent of the calculations already performed. The terms have been calculated in twenty-one groups, the order of calculation being indicated by the number in the first column. The second column gives the multiple of the eccentricities, inclination, and ratio of parallaxes that is common to each coefficient of the group. The third column gives the fundamental argument from which all the other arguments are derived by the addition or subtraction of multiples of twice the elongation, Delaunay's notation being used. The fourth column gives the number of terms calculated. The fifth column gives the approximate value in arc of the largest coefficient, and the sixth column the value of the largest coefficient indicating a disturbance from elliptic motion. The last column gives the value in arc of the last significant figure, and where, as often happens, the coefficients of a group have been calculated to a different number of decimal places, then the number given in this column corresponds to the coefficient calculated with least accuracy.

Reference Number.	Characteristic.	Argument.	Number of Terms.	Approximate value in arc of the largest coefficient (1) including (2) excluding purely elliptic terms.		Value of unity in the last figure given in millionths of a second of arc.
1*	1	0	13	206265″	1800″	0·0002
2	e	$\pm l$	18	17000	3000	2
3	e'	$\pm l'$	21	350	350	0·4
4	a	D	9	80	80	0·05
5	k	F	11	9000	300	0·01
6	e^2	$\pm 2l$	21	240	170	3
7	e^2	0	11	340	100	3
8	ee'	$\pm (l + l')$	21	140	140	4
9	ee'	$\pm (l - l')$	22	100	100	4
10	e'^2	$\pm 2l'$	18	6	6	0·6
11	e'^2	0	10	2	2	0·6

19	ke'	F + l'	10	1	1	0·01
20	ke'	F − l'	11	0·4	0·4	0·01
21	ka	D + F	10	4	4	0·02

* Calculated by Dr. Hill.

Dr. Brown gives as the approximate values of the constants in the third column of the above table

$$e = 0{\cdot}11 \qquad e' = 0{\cdot}017 \qquad k = 0{\cdot}045 \qquad a = 0{\cdot}0026$$

It will be seen that the terms calculated include all that ar algebraically of the second order. The ratio of the parallaxe is here considered as being of the first order. The terms depending on the square of this ratio, it will be noticed, are insensible to observation. This is fortunate, as the terms cannot be corrected for the neglected mass of the moon.

We think that the results selected for publication are a little too meagre. They consist of the actual solution itself, and one other set of terms whose calculation divides the labour of each section into two fairly equal halves. We hope that an appendix will be finally published in which the value of every auxiliary quantity will be given. Such an appendix might be of great use in other investigations. It would also be of immense value should there ever be a suspicion of error in Dr. Brown's own calculations, for it would then be far easier to establish the fact of such an error, should one ever creep in, and it would entail less labour to carry through the correction.

MARINE BIOLOGY AT THE BERMUDAS.

AN expedition of the biological department of New York University went to the Bermudas a few months ago to study the marine fauna, and to investigate the conditions offered for the establishment of a permanent biological station there. The party has now returned, and an account of the observations made is contributed by Prof. C. L. Bristol to *Science*, from which source the following particulars have been derived:—

The most attention was given to a search for the various forms and a careful survey of the general conditions subtending their abundance and collection, so that, taken as a whole, the work might prove a reconnaissance and furnish knowledge for future investigations. In this the expedition was fairly successful and would have been much more so but for a long spell of south-west wind which prevented off-shore work, excepting for a few days. Our work was confined mainly to the lee shores, and here we were greatly rewarded. Of corals the genera *Diploria*, *Meandrina*, *Astrea*, *Siderastrea*, *Porites*, *Isophyllia*, *Oculina* and *Mycedium* were found; of Gorgonians, *Rhipidogorgia* and *Gorgonia*. The Actinaria are very abundant and our collections are numerous. We found but few hydroids and a millespore coral. The Medusæ and Hydro-Medusæ are very abundant in the still waters of Harrington Sound. The Echinoderms are exceedingly interesting and abundant. The Holothuria are represented by the genera *Holothuria*, *Semperia*, *Stichopus*, the last being very abundant. The Asteroidea are few, and are represented by one species of *Asterias* and one of a new genus not yet determined; the Ophiuroidea by several genera. The Echinoidea are represented by *Cidaris*, *Diadema*, *Hipponæ*, *Echinometra*, *Toxopneustes*, *Mellita* and one new genus. The Crustacea are numerous and exceedingly interesting. Our collections will be studied by Dr. Rankin, who will report on them later.

The Mollusca of the archipelago number, according to Heilprin, about 170 marine forms and thirty terrestrial. Among the cephalopoda are *Octopus* and *Argonauta*. The naked *Aplysia* is fairly abundant, and numerous other naked molluscs are found in Harrington Sound.

The Annelids are not as numerous in the places we searched as we expected, but those we found are new to us and the genera are not yet determined. The sponges are very numerous in genera and plenty in individuals. The Tunicates are exceedingly numerous and offer a rich field for investigations. *Amphioxus* is reported, but we had no opportunity to search for it. The abundance and beauty of the Bermuda fishes is notorious. Dr. Bean is making a study of them, carrying on the work started by his colleague the late Dr. G. Brown Goode. Incidental to the main work of the expedition we undertook to furnish the Aquarium in New York with live specimens of some of these fishes, and thousands of visitors to that institution testify to their beauty and gracefulness. This part of the work was by no means the least interesting. We installed four large tanks and a pumping engine on White's Island, in the harbour of Hamilton, and acclimatised the fish before transferring them to the steamship. On board the boat the fish were supplied with running water, thanks to the kindness of the Quebec Steamship Company, and no small part of our success was due to the generous and skilful aid given us by the Chief Engineer, Mr. Ritchie. Under these favourable conditions our loss was slight, and another season will be much less. It is interesting to note that our efforts to bring invertebrates alive failed in every case but one, though we could keep them in prime condition until we struck the polluted waters of the coast, when they died quickly. Our failures, however, have suggested remedies, and next year we hope to show *Octopus*, *Palinurus*, *Ibacus*, *Aplysia* and the sea-anemones, as well as the fishes. The fishes thrive in the Aquarium, although the water is several degrees cooler than they are accustomed to, and the salinity much less. There would be little difficulty apparently in carrying them from New York across the Atlantic, if that were desirable, under the same conditions that we carried them from Bermuda.

Our hasty survey strengthens the idea of establishing a station, and we are planning to have one in working condition by the summer of 1899, if not before. It will have two stories, the lower given up to aquaria, as at Naples, and open to the public during the winter at a small fee; the upper story will be fitted up for a laboratory, and while under the charge of the University will be open to any one competent to carry on an investigation in botany or zoology. It is not intended to rival any of the stations on the Atlantic coast, but to supplement them, and to afford opportunity to investigators of America and Europe to study the flora and fauna of a tropical horizon with ease and comfort. The healthfulness of the place is testified by the yearly visitation of over two thousand guests who spend the winter months there. Malaria is unknown, as is also prostration by heat. The climate during June and July is not disagreeable, the thermometer rarely going up beyond 82°.F.

Another project in hand with the station at the Bermudas is the exploration of the West Indies with the Bermudas as a base. Two lines of steamers connect the islands with the West Indies, and the investigator starting on them equipped from the appliances of the station may make a rapid collecting trip to a desired place, and return to work over his material under the more favourable conditions at the station.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The examination for University Mathematical Scholarship and Exhibition will begin on January 20, 1898.

At the Junior Scientific Club on Friday last, November 19, Mr. A. C. Le Rossignol (Exeter) read a paper on "Nitro-explosives." Mr. H. Balfour (Trinity), exhibited a series showing the ancient and modern use of bones of animals as skates. Mr. N. V. Sedgwick (Ch. Ch.) was in the chair.

The regulations for carrying into effect the provisions of the statute relating to the training of teachers are as follows:—I. To obtain the certificate the candidate shall (1) satisfy the authority appointed by the delegates in practical work done under supervision in Oxford; (2) present a record in writing, satisfactory to the delegates, of lessons prepared and given by him, or her, during the training course in Oxford; (3) have taken a further probationary course of teaching in some school appointed by the delegacy; such course to include not less than one hundred lessons, and the report of this work to be signed by the head master or mistress; (4) pay a fee of 2*l.* 2*s.* when the diploma is awarded. II. In the case of candidates already teachers (with the exception of those who shall have passed, or taken honours at, the second public examination after Trinity Term, 1898), the delegacy will certify that a candidate has satisfied them of proficiency in the practice of teaching, provided that the candidate (1) has taught for a year in a secondary school approved by the delegacy; (2) has attended at least one holiday course held under the authority of the delegacy; (3) has satisfied the persons appointed by the delegacy of his, or her, proficiency in the practice of teaching; (4) shall pay a fee of 3*l.* 3*s.*

A HALL of physics, in connection with Syracuse University, will, it is expected, be built next year, the sum of 5000*l.* having already been subscribed for the purpose.

SIR WILLIAM MACCORMAC, the President of the Royal College of Surgeons, England, has been appointed a Governor of the Mason College, Birmingham, for five years.

THE new chemical laboratory building of the University of Berlin, which is at present in course of erection, will, it is stated, contain four large laboratories and twenty-five research rooms, and accommodate 250 students. Its cost will be about 50,000*l.*

AMONG a number of bequests by the late Sir Thomas Elder, of Glan Osmond and Adelaide, South Australia, are:—4000*l.* to Prince Alfred College, Adelaide; 2000*l.* to Way College, Adelaide; 25,000*l.* to Adelaide University; and 20,000*l.* to the Medical School of Adelaide University.

MANUFACTURERS having at heart the advancement of technical education should emulate the action of Messrs. Brunner, Mond, and Co. This firm voluntarily tax themselves to the extent of one penny in the pound on their works at Anderton, Barton, and the rural portion of Winnington, in the interests of technical education in Cheshire.

AT a meeting of the Council of the Royal College of Surgeons, England, on November 11, Felstead School and Watford Endowed Schools were added to the list of recognised places of instruction in chemistry, physics, and practical chemistry; and the South-west London Polytechnic Institute, which was already recognised for instruction in these subjects, was added to the recognised places of instruction in elementary biology.

THE Court of the Drapers' Company have approved the plans of a new building at Oxford, which will be the future home of the Ratcliffe Library if the authorities at Oxford accept them. The cost of the new structure will be 18,500*l.* The Ratcliffe Library was founded by Dr. Ratcliffe considerably over a century ago, but the space it now occupies will be absorbed by the extension of the medical school. The Drapers' Company, in the interests of education, has undertaken to erect the new building, the plans of which have been prepared for the Company by Mr. T. G. Jackson, R.A.

AMONG recent appointments abroad, we notice the following: Dr. Theodore Curtius, of Bonn, to succeed the late Prof. Victor Meyer at Heidelberg; Mr. G. S. Wilkins to be professor of civil and mining engineering at the University of Alabama, and Dr. John Y. Graham to be professor of biology at the same institution; Dr. Max von Frey, of Leipzig, to be professor of physiology at the University of Zürich; Dr. Kraus to be professor of botany at the University of Halle; Dr. Max Dessoir to be associate professor of psychology at the University of Berlin; Dr. Lothar Heffter to be associate professor of mathematics at the University of Bonn; and Dr. Brikencajer to be associate professor of mathematics at the University of Krakau.

THE extent to which County and County Borough Councils in England are working in connection with secondary schools may be seen in a tabular statement published in the current *Record of Technical and Secondary Education*. The tables go to show that during the year 1896–97, sixty-three local authorities gave direct or indirect assistance to three hundred and twenty-eight individual secondary schools to the extent of 144,871*l.*, this sum including the value of scholarships and exhibitions granted for pupils proceeding from secondary schools to higher institutions. Other ways in which the sum referred to was expended were in capitation grants, for teaching staff, maintenance, apparatus, &c., and buildings.

THE Birkbeck Science Society has just been formed in connection with the Birkbeck Institution, London, and purposes holding meetings on the first and third Saturdays of each month, for the reading and discussion of papers on scientific and philosophical subjects. It is also intended to make frequent excursions to places of scientific interest, especially chemical and physical works. It is further intended to publish a journal, containing abstracts of the papers read before the society, together with reports of the scientific excursions. The first meeting of the Society was held on Saturday, in the Chemical Lecture Theatre of the Institution, when a large number of past and present students were present. The Principal of the Institution, Mr. G. Armitage-Smith, occupied the chair, and after welcoming the Society on behalf of the governing body, made some very appropriate and interesting remarks about the value of scientific study. An interesting and instructive paper on "Cavendish and his Work" was then read by Dr. J. E. Mackenzie. The lecturer started by picturing the state of science at the beginning of Cavendish's work, and traced it down to the present day, showing that the 1 per cent. of gas which always remained after his experiments with air, was in reality the argon discovered by Lord Rayleigh and Prof. Ramsay. The Secretary's report was very encouraging, showing that although the Society had only been in existence for about three weeks, it now numbered more than seventy members. The next meeting of the Society will take place on Saturday, December 4, when Mr. R. S. Clay will deliver an experimental lecture, entitled "Soap Bubbles."

THE opening meeting of the winter session of the General Medical Council was held on Tuesday, Sir William Turner presiding in the absence of Sir Richard Quain, the president. The chairman read a letter from the president expressing regret at the fact that, though his health had improved, he could not undertake the risk of presiding at the meetings during the present session. In the course of his communication Sir R. Quain referred to the progress that had been made with regard to the question of disciplinary or penal powers exercised by the various licensing bodies. Following the example of the University of Cambridge, the University of Durham had now obtained a charter under which it had the power of taking away any degree from a graduate who had been convicted of a crime for which he had been sentenced to penal servitude or imprisonment. Similar steps, he was informed, were being taken by the Victoria University, its court having decided to make application for the necessary amendment of its charter; so that in a very short time that University also would be in possession of extended powers. In Scotland, also, some further steps had been taken in regard to this question. The Universities of Aberdeen and St. Andrews would, no doubt, be prepared to adopt a course of action similar to that taken by Edinburgh and Glasgow. With regard to the new edition of the "British Pharmacopœia," the arduous and important work of preparation that had occupied about three years, was now well nigh finished, and if the Council accepted the draft that would be placed before them in the course of the present session it might be expected that the work would be published at an early date.

SINCE the passing of the Local Taxation Act (1890), twenty-three municipal science and art and technical schools have been established. In a number of localities (states the *Record*) the technical schools have been, or will be, erected as a part of general schemes which include the provision of other institutions for public or municipal use, for example as free libraries, museums, art galleries, gymnasiums, &c. In several localities, on account of the development of the work since the erection of the technical institutions, considerable extensions have been, or are about to be, made to the buildings; the total sum spent or involved for these extensions in the seven districts amounts to over 33,000*l.* In some cases local science and art and technical schools or classes have been transferred to the respective local authorities for municipal management and control since the passing of the Technical Instruction Act, 1889; in Chesterfield the local technical institution, which was erected at a cost of 13,000*l.*, was subsequently purchased by the Corporation for the sum of 4000*l.* In Lancaster a splendid institution was built and fitted up and presented to the Corporation by Sir Thomas Storey, and in Northwich and Winsford sites were secured and technical schools were erected and furnished at the expense of Sir Joseph Verdin, Bart. The total amount of money which has been provided by these means for the erection of schools and institutions in seven of these localities (excluding Lancaster) is as much as 81,000*l.*, the schools in Burslem, Lancaster, and Southport serving as permanent memorials of Her Majesty the Queen's jubilee of 1887. Excluding Bridgwater and Lancaster, the total sum involved in the erection of technical schools in the thirty-six boroughs and urban districts not included in the above statement is as much as 331,000*l.*

SCIENTIFIC SERIALS.

Symons's Monthly Meteorological Magazine, November.—The rainfall of October, 1897. This was so exceptionally small that all records received up to date showing a total fall of less than an inch for the month have been tabulated. The lowest values, expressed in inches, are found in the extreme south-east of Kent, ·32; Sussex, ·34; Hants, ·49; Essex, ·51; Suffolk, ·59; Surrey, ·60. At least a quarter of the stations quoted, spread over England and Wales, nearly 240 in number, record less than an inch.—Austrian hydrography. This is a summary of the reports of a comparatively new organisation, dealing with the rainfall of the principal watersheds for the year 1895; the stations number between two and three thousand, and the results are contained in fifteen large folio parts. Each part, except the introductory one, includes a large-scale shaded rainfall map, and the whole work probably surpasses anything of the kind in any other country.

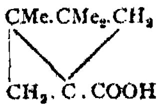
Wiedemann's Annalen der Physik und Chemie, No. 11.—Retardation of spark discharge, by E. Warburg. The period elapsing between the establishment of the necessary difference of potential and the corresponding discharge is called the "retardation." It varies from a few minutes to a fraction of a second, and is due to a non-luminous partial discharge. This preliminary discharge is greatly influenced by ultra-violet light, and also by a magnetic field.—Photo-electric properties of fluorspar and selenium, by G. C. Schmidt. Although fluorspar acquires a positive charge in some parts under the influence of light, and a negative charge in other parts, it only dissipates negative charges under the action of light, and even selenium shows no sign of dissipating a positive charge.—Mutual influence of kathode rays, by J. Bernstein. The apparent repulsion between two kathode beams running side by side is due to some action of the metallic kathode upon the origin of the other beam, and not to any mutual action of projected particles. This may be proved by allowing them to proceed parallel to each other from opposite ends of the tube, when their path remains straight.—On the nature of the salts coloured by kathode rays, by R. Abegg. The coloration of NaCl and KCl salts by kathode rays is not due to the formation of sub-chlorides, since no chlorine is evolved. It is a physical change.—On the carbon electric arc, by R. Herzfeld. The counter E.M.F. produced by the air is not due to the deposition of carbon particles on the kathode, since they may be deflected by a strong electric field without affecting the E.M.F. The growth on the kathode is due to the lack of oxygen necessary for the complete combustion of the carbon.—Conductivity of electrolytes for rapid oscillations, by J. A. Erskine. An oscillator is placed in a basin filled with petroleum, and another dish containing the resonator immersed in the electrolyte is placed on the top of it. The electric resistance of the electrolyte is directly proportional to the thickness required to produce a given amount of damping.—Absorption of electric oscillations by luminescent gases, by E. Wiedemann and G. C. Schmidt. Gases excited to luminescence in a vacuum tube screen other tubes from similar excitation, but flames do not, neither does the dark kathode space. A similar screening is produced by Goldstein's "canal rays."

Meteorologische Zeitschrift, October.—Some results of the five years' observations on the Eiffel Tower, by A. Woeikof. The author compares the daily periods of temperature and wind force for certain selected months; in the winter the minimum wind force at the summit of the tower occurs about the time of the highest daily temperature; while in summer it takes place considerably earlier, about 9h. or 10h. The force then increases gradually until the time of highest temperature, and afterwards more rapidly, until evening. The times of the maxima at the summit and on the ground do not exhibit any decided seasonal range, but in the case of the minima a seasonal range is clearly shown. During May to July the mean time is 1·3 hours earlier than during November to February. At the summit the occurrence of the minimum is earlier in summer than in winter, and the interval is greater, viz. 4·5 hours. An explanation of these phenomena is suggested by Dr. Woeikof.—The total variation of temperature in the Arctic and Equatorial oceanic climate, by A. Woeikof. The variations considered are those shown by hourly observations for certain representative months for Batavia and Sagastyr (mouth of the Lena). Dr. Woeikof finds that summer and spring have nearly the same variation in the Equatorial and Arctic climate, and that the uniformity of summer temperature in polar regions is exhibited by this investigation. The total variation is even somewhat smaller than at Batavia, while the non-periodic portion is not twice as great.—Dr. W. Trabert contributes an article on the extraordinary rainfall in Austria between July 26 and 31 last, which caused destructive floods in several districts.—Among the smaller notices, Prof. G. Hellmann gives a formula for the conversion of Fahrenheit to Centigrade degrees, which is simpler than that usually employed, viz.: to half the difference between the reading and 32° add the tenth and hundredth part of this difference, *e.g.* $\frac{74-32}{2} = 21 + 2{\cdot}1 + {\cdot}2 = 23^{\circ}{\cdot}3$, the value given in the tables. For an explanation of the rule we refer our readers to the original notice.

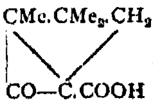
SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, November 4.—*Prof. Dewar, President*, in the chair. The following papers were read:—On the properties of liquid fluorine, by Profs. Moissan and Dewar (see page 82).—The liquefaction of air and the detection of impurities, by Prof. Dewar. The author has devised an apparatus for ascertaining the proportion of any gas in air that is not condensible at about −210° C. under atmosphere pressure, or is not soluble in the liquid air produced; the air to be examined is cooled in a tube immersed in a reservoir, which can be continuously replenished with liquid air boiling under diminished pressure. The gas which does not condense under these conditions can be subsequently collected and examined, or the liquefied portion of the air can be boiled in the condensing tube and the gas collected over mercury. On thus condensing 70 litres of the gas issuing from the King's Well at Bath, which Rayleigh has shown to contain 0·12 per cent. of helium by volume, a liquid was obtained which, when boiled, gave off first a gas containing about 50 per cent. of helium. It is concluded that helium is less soluble in liquid nitrogen than hydrogen is in liquid air, and that by proceeding as above helium can be separated from a gas in which it is present to the extent of only one part per thousand; it would seem, further, that hydrogen and helium have about the same volatility.—The absorption of hydrogen by palladium at high temperatures and pressures, by Prof. Dewar. The author, after summarising his previous work on the absorption of hydrogen by palladium, describes experiments made with the object of ascertaining whether the metal absorbs the gas at high temperatures and pressures; palladium does not absorb hydrogen under atmospheric pressures at above 145° C. A rod of palladium, weighing 119 grams, and occupying 10 c.c., was placed in a gas-tight steel cylinder, connected with a manometer, a compressed hydrogen cylinder, and a blow-off cock; the vessel containing the palladium could be heated in a bath of fusible metal. It was found that the palladium absorbed over 300 times its volume of hydrogen at 420° under 80 atmospheres pressure, whilst it absorbed 300 times its volume of the gas at 500° under 120 atmospheres. The experiments have led to the deduction of a number of interesting thermal constants for the absorbed hydrogen.—On some yellow vegetable colouring matters, by A. G. Perkin. The *Rhus rhodanthema*, a tree indigenous to New South Wales, contains fisetin, $C_{15}H_{10}O_6$, and a glucoside of fisetin, $C_{36}H_{30}O_{16}$ resembling fustin, the fisetin glucoside present in *R. cotinus*.—Naphthylureas, by G. Young and E. Clark. The mononaphthylureas may be prepared by treating the naphthylamine hydrochlorides with potassium cyanate, and readily become converted into the symmetrical dinaphthylureas. — Benzoylphenylsemicarbazide, preliminary notice, by G. Young and H. Annable. Benzoylphenylsemicarbazide exists in three different forms, melting at 202–203°, 205–206°, and 210–211° respectively.—Sulphocamphylic acid, by W. H. Perkin, jun. From the results of an investigation of sulphocamphylic acid, the author assigns the following probable constitutions to isolauronolic and isolauronic acid respectively:—



and



.

Geological Society, November 3.—Dr. Henry Hicks, F.R.S., President, in the chair.—The Secretary announced that Lady Prestwich had presented to the Society a half-length portrait in oils of the late Sir Joseph Prestwich, painted by Mr. W. E. Miller.—Mr. W. W. Watts gave details of some interesting geological features recently exposed at the new sewerage works at Carshalton, Surrey, now being made by the Urban District Council. These excavations are situated at a spot which on the Geological Survey map is coloured as London clay; and the features of the ground fully justified this colouring. The excavations, however, have shown that there are loamy and sandy beds of a light yellow colour, some 14 or 15 feet in thickness, and apparently occupying a hollow in the London clay. At the base these sandy beds become dark and clayey in some places, and include flints and pebbles, while below this is the London clay. In the dark pebbly layer were found a large skull, a piece of a tusk, and a number of smaller bones, which Mr. E. T. Newton has determined to be a piece of elephant-tusk, the skull (31 inches long) of *Rhinoceros antiquitatis* with some of its limb-bones; while the smaller bones represent two or perhaps three horses. Although the teeth of the rhinoceros are wanting, the skull is otherwise very perfect; and, bearing this in mind, as well as the fact that certain of the limb-bones were also found, and that *Elephas* is represented by the tusk, and all three (it is said) at a depth of 14 or 15 feet, little room is left for doubting that we have here at Carshalton a Pleistocene deposit of a somewhat unusual character, and at a spot where it was not before suspected. Mr. Whitaker, who was responsible for the geological mapping of this district, pointed out how the general configuration of the district gave no clue to the presence of this deposit of loamy sand, which occurred on a gentle slope, and that even now it was only possible to mark it on the map as an oval patch round the excavations with uncertain boundaries. The drift shown, moreover, differs from that of the neighbourhood in that the latter is essentially gravel, while the former is sand, with loamy beds, but, as a rule, not stony, so that there are no surface-indications of gravel. The mammalian remains are now preserved in the Museum of Practical Geology.—Lieut.-General McMahon having taken the chair, the President made a communication regarding very similar deposits to those above described occurring in north-western Middlesex. Some years ago he described sections in glacial drift on the Hendon plateau exposed during sewerage operations. More recently the sewers have been carried on at lower levels between Hendon and Edgware, and numerous remains of the mammoth and rhinoceros have been found resting on an eroded surface of London clay, and covered over by about 7 feet of stratified sands and gravels and brick-earth. These deposits were found to spread out for considerable distances over the plain, and to be cut through also by the Silke stream, a tributary of the Brent. This area has hitherto been supposed to consist almost entirely of London clay, but the sections have now shown that the brick-earth which, in many respects, simulates the London clay, is underlain by deposits which must be classed as of Pleistocene age.—The President then resumed the chair, and Mr. H. B. Woodward called attention to a block of quartzite from Criccieth in Carnarvonshire, which had been sent for exhibition by Mr. G. J. Day. The rock contained a band of disrupted clayey material which presented on the surface of the block a rude resemblance to hieroglyphics. He thought that the curious structure had been produced on a sea-shore bounded by clay cliffs, where a film of mud had been spread over the sands; and that the mud had dried and curled up before other layers of sand had been accumulated on the top of it. Similar phenomena might be produced at the present day on the Cromer coast, where thin films of mud were in places spread over the sands of the sea-shore. It had been suggested that the appearances in the Criccieth stone might have been produced in the original deposit during the irregular solidification of the sand and its included layer of mud. The rock itself was regarded by the President as probably derived from the Harlech grits, in which he had observed somewhat similar features.—Mr. Bauerman, as one of the three delegates appointed by the Council on behalf of the Society to attend the recent International Geological Congress, held at St. Petersburg, gave a short account of the work of the Congress, dwelling more particularly on the excursion to the Ural Mountains, in which he had taken part.—The following communication was read: A contribution to the palæontology of the decapod Crustacea of England, by the late James Carter. This paper deals mainly with the Brachyura. The author describes several new species belonging to the genera *Nephrops*, *Gebia*, *Homolopsis*, *Ranina*, *Mithracia*, *Neptunus*, *Actæopsis*, and *Goniocypoda*. The genera *Gebia*, *Ranina*, and *Neptunus* have not been previously recorded from British rocks. *Diaulax* is for the first time identified from the Tertiary strata, a single specimen having been found in the Middle Headon. *Platypodia Oweni*, Bell, is now referred to the genus *Diaulax*; and *Palæocorystes Broderipi*, Bell, to the genus *Eucorystes*. As a result of the careful study of large series of specimens in various collections, the author is able to give much additional information concerning the morphology of several species.

Zoological Society, November 16.—Dr. Albert Günther, F.R.S., Vice-President in the chair.—The Secretary read some notes, made by Mr. A. Thomson, Head-Keeper, on the breeding of two species of Glossy Ibis (*Plegadis guarauna* and *P. falcinellus*) in the Society's Gardens, and made remarks on the differences in their plumages. The Secretary also exhibited an egg of the Brazilian Cariama (*Cariama cristata*), laid in the Society's Gardens, and read some notes made by Mr. A. Thomson, Head-Keeper, on the breeding of this bird.—Mr. Sclater gave an account of some of the more interesting animals observed by him during a recent visit to the Zoological Gardens of Cologne, St. Petersburg, Moscow and Berlin.—A note was read from Messrs. Oldfield Thomas and R. Lydekker, stating that during the preparation of their paper on the dentition of the Manatee, published in the last part of the *Proceedings*, an important memoir by Dr. C. Hartlaub on the subject, in which some of their conclusions had been anticipated, had been overlooked.—Mr. R. Lydekker, F.R.S., exhibited a skin of the Blue Bear of Tibet (*Ursus pruinosus*), described and figured in the Society's *Proceedings* (*P. Z. S.*, 1897, p. 412, pl. xxvii.), and a sketch of the Altai Deer (*Cervus eustephanus*) taken from a specimen in the menagerie of the Duke of Bedford at Woburn Abbey.—A communication by Mr. George P. Mudge, "On the Myology of the Tongue of Parrots," was read by the author. Specimens of six different species of the *Psittacidæ* had been examined, and a detailed description of the muscles of each of them was given in this paper.—A communication from Mr. E. T. Browne, "On British Medusæ," was read. It was a continuation of a previous paper, entitled "On British Hydroids and Medusæ," published in the *Proceedings* for 1896. Eight species were treated of at length.—Dr. A. G. Butler enumerated the species (138 in number) contained in three consignments of butterflies collected in Natal in 1896 and 1897 by Mr. Guy A. K. Marshall, and gave the dates of the capture of the specimens, the localities where they were found, and other interesting notes concerning them. One new genus (*Chrysoritis*) and one new species (*Cacyreus marshalli*) were described. A communication from Mr. Edgar R. Waite, of the Australian Museum, Sydney, "On the Sydney Bush-Rat (*Mus arboricola*, W. S. Macleay)," was read. It treated of the habits of the animal in a wild state and of its anatomical characters.—A third portion of a paper on the spiders of the Island of St. Vincent, by M. E. Simon, was communicated by Dr. D. Sharpe, F.R.S., on behalf of the committee for investigating the fauna and flora of the West Indian Islands. Of the species enumerated forty-six were described as new, which included three new genera, viz. *Mysmenopsis*, *Homalometa*, and *Mesobria*.—Prof. Alfred Newton, F.R.S., exhibited some specimens of new or rare birds' eggs, and read some notes upon them. Amongst these were the first properly authenticated examples of the eggs of the Curlew-Sandpiper (*Tringa subarquata*) obtained by Mr. Popham on an island in the mouth of the Jenisei River in July last. Other eggs exhibited were those of *Turdus varius*, *Chasiempis sandvicensis*, *Himatione virens*, *Emberiza rustica*, and *Podoces panderi*.

Linnean Society, November 4.—Dr. A. Günther, F.R.S., President, in the chair.—Mr. F. G. Jackson, leader of the Jackson-Harmsworth Polar expedition, exhibited a series of lantern-slides, illustrating some zoological observations of the expedition, the most noteworthy being views of the hibernaculum of the polar bear and of the breeding haunts in Franz Josef Land of the ivory gull (*Pagophila eburnea*), the eggs of which were also shown.—Mr. H. Fisher, botanist of the expedition, brought for exhibition a collection of plants made by him in Franz Josef Land, the consideration of which was deferred for want of time.—Mr. Reginald Lodge exhibited some lantern-slides of marsh birds, their nests, eggs, and young, from photographs recently taken in Spain and Holland.—Sir John Lubbock, Bart., M.P., read a paper on the attraction of flowers for insects, which dealt chiefly with the points raised in three recently published memoirs by Prof. Plateau, who had attempted to show that the scents and not the colours of flowers serve to attract insects. Sir John Lubbock explained that his view, like that of Sprengel and Darwin, was that to insects flowers were indebted for both their scent and colour. Not only had the present shapes and outlines, colours, the scent, and the honey of flowers been gradually developed through the unconscious selection exercised by insects, but this applied even to minor points, such as the arrangement of lines, and the different shades of colour. Prof. Plateau had recorded a series of experiments on the dahlia, in which he showed that bees come to these flowers even when the ray-florets have been removed. Discussing this point, Sir J. Lubbock said it was somewhat singular that he should have selected as proving that insects are entirely attracted by scent a flower which had, so far as he knew, no scent at all. He gave several reasons for disputing the conclusions drawn by Prof. Plateau from his experiments, and recorded others made by himself which refuted them. He had selected species of flowers in which the scent is in one part and the coloured leaves in another, as, for instance, the *Eryngium amethystinum*. This flower is surrounded by brilliant blue bracts; and he found that if the two parts were separated, the bees came more often to the bracts than they did to the flowers themselves. He maintained, therefore, that the observations of Prof. Plateau did not in any way weaken the conclusions which had been drawn by Sprengel, Darwin, and others, and that it was still clear that the colours of flowers serve to guide insects to the honey, and in this way secure cross-fertilisation.—Mr. W. C. Worsdell communicated a paper on transfusion-tissue, its origin and functions in the leaves of Gymnospermous plants.

PARIS.

Academy of Sciences, November 15.—M. A. Chatin in the chair.—Reaction of hydrogen upon sulphuric acid, by M. Berthelot. Sulphuric acid absorbs hydrogen completely at 250°, and even in the cold, during two months, 75 per cent. of the hydrogen present was absorbed, with production of a corresponding amount of sulphur dioxide. This reaction does not take place with the diluted acid. A thermo-chemical study shows that the dilution of the acid changes the thermal sign of the reaction.—Influence of oxygen upon the decomposition of the hydracids by metals, and especially by mercury, by M. Berthelot. Although pure hydrogen chloride may be kept over mercury for several years without change, in the presence of oxygen there is a slow absorption, as a result of which the acid is wholly absorbed according to the equation

$$4HCl + O_2 + 4Hg = 2Hg_2Cl_2 + 2H_2O.$$

A similar reaction takes place between mercury, hydrogen sulphide, and oxygen. In both these cases there is an evolution of heat during the reaction.—Direct action of sulphuric acid upon mercury at the ordinary temperature, by M. Berthelot. Mercurous sulphate and sulphur dioxide are produced after long standing at ordinary temperatures.—Observations on the swarm of shooting stars, made at the Observatory of Paris, during the nights of November 13–14, 14–15, 1897, by M. Lœwy.—Influence of surfusion upon the freezing point of solutions of potassium chloride and sugar, by M. F. M. Raoult. The experiments quoted now definitely show that the molecular lowering of the freezing points for potassium chloride and sugar have limiting values agreeing with the predictions of Arrhenius.—On the integration of the equations of heat, by M. Le Roy.—Observations of the shooting stars at the Observatory of Meudon, by M. Hansky.—Observations on this communication, by M. J. Janssen.—The mechanical principles involved in the practical application of the mercury bath as a means of obtaining a true vertical, at the Paris Observatory, by M. Maurice Hamy.—On a generalised displacement in which all points describe spherical trajectories, by M. Ernest Duporcq.—On the theory of complete functions, by M. Erik Schou.—On the transmission of energy at a distance. Application to rotatory polarisation, by M. André Broca.—On the coefficients of expansion of gases, by M. A. Leduc. From the experimental results on the densities of gases previously given, a formula is derived for the true coefficient of expansion at 0° C. under a pressure of ϖ cm. of mercury. This formula is applied to some twenty-three gases, and the figures obtained compared with the experimental results of M. P. Chappuis.—Action of water upon phosphorus trichloride, by M. A. Besson. Evidence is adduced of the existence of a phosphorus oxychloride, POCl, analogous to NOCl. It is formed by the action of a small quantity of water upon an excess of phosphorus trichloride, according to the equation

$$PCl_3 + H_2O = 2HCl + POCl,$$

and is separated from the excess of the trichloride, by distillation in a vacuum. POCl forms a waxy solid, of the consistence of paraffin, which is insoluble except in PCl_3. The yield is very small, never exceeding 0·2 to 0·5 gr. per kilogram of PCl_3 used.—On cerium, by M. O. Boudouard. By fractional crystallisation and precipitation of the acetate and sulphate of cerium it is found that cerium oxide is contaminated with small quantities of another earth possessing a lower atomic weight.—On the preparation of strontium sulphide by means of hydrogen sulphide and strontia or strontium carbonate. Influence of temperature, by M. José Rodriguez Mourelo.—Production of volatile fatty acids from the waters used in the *désuintage* of wool, by MM. A. and P. Buisine. The acids obtained include acetic, propionic, butyric, valerianic, and caproic, the two first being the chief constituents.—On the decomposition of chloroform, bromoform, and choral by aqueous potash, by M. A. Desgrez. An aqueous solution of potash attacks chloroform slowly, with production of carbon monoxide. Light hastens the reaction. Bromoform behaves similarly, except that being much less soluble in water than chloroform, the action is less. Iodoform is not affected under the same conditions.—On silver cyanamide, by M. Paul Lemoult. A thermo-chemical paper.—Observations on the crabs of the family of the Dorippidia, by M. E. L. Bouvier. A contribution to the study of the evolution of the deep-sea crabs. The close analogy between the species found in West Indian seas and the Eastern Pacific leads to the conclusion that at no very distant period the oceans were connected at Panama.—On a new type (*Metchnikovella*) of organisms parasitic to *G. spionis*, Köll, by MM. Maurice Caullery and Félix Mesnil.—On a bacterium pathogenic for Phylloxera and for certain Acarians, by M. L. Dubois.—On the determination of sex in hemp, by M. Molliard. From a fixed number of hemp seeds, an alteration of the conditions of growth may cause an alteration in the proportion of male and female plants produced.—Action of mineral salts upon the form and structure of the lupin, by M. Dassonville. The presence of dissolved salts, among other effects, increases the number and diameter of the vessels, and retards lignification in all the organs of the lupin.—On the composition of the oat, by M. Olivier de Rawton.—Composition of buck-wheat, by M. Balland.—On the use of calcium carbide against black rot, by M. G. Rodier.

NEW SOUTH WALES.

Linnean Society, September 29.—Dr. J. C. Cox, Vice-President, in the chair.—Revision of the Australian *Curculionidæ* belonging to the subfamily *Cryptorhynchides*, Part i., by Arthur M. Lea. The subfamily *Cryptorhynchides* being in considerable confusion, it is proposed to examine and redescribe all the Australian genera and species referred to it. The genus *Poropterus* is treated of in the present communication, seventeen species being described as new.—On a new species of *Eucalyptus* from the Sydney district, by Henry Deane and J. H. Maiden. This is a tree of about thirty feet in height, with scaly bark and red timber. The seedling-leaves are ovate to ovate-lanceolate and always alternate. The veins and midribs are reddish and conspicuous. The transverse veins are numerous and fine, making an angle with the midrib of about 50°. The fruits are nearly hemispherical, with a slight tendency to constriction of the orifice, about four lines long by three lines deep, with a sunk rim. The anthers open by pores, showing the affinity of the species, in this direction, to *E. hemiphloia*, and the "Boxes." Its bark bears a superficial resemblance to that of *E. corymbosa*, and, because of its scaly nature, the name of *E. squamosa* is proposed for it.—Descriptions of some new Araneidæ of New South Wales, No. 8, by W. J. Rainbow. Ten new species are described and figured, of which four are referable to the genus *Epeira*, three to *Argiope*, and one each to *Dicrostichus*, *Cheiracanthium*, and *Attus*. In addition to these, numerous specimens of architecture of spiders are described, and some figured, the families illustrated being the *Epeiridæ*, *Drassidæ*, *Attidæ*, and *Thomisidæ*.—Note on the genus *Aphritis*, Cuv. and Val., by J. Douglas Ogilby. The author contends that whereas five different fishes have been assigned to the genus *Aphritis*, C. and V., by various authors, these are referable to but three distinct species, each of which represents a monotypic genus; he distributes them as follows: *A. porosus* and *A. undulatus* lege *Eleginops maclovinus* (C. and V.), Gill; *A. urvillii* and *A. bassii* lege *Pseudaphritis urvillii* (C. and V.); *A. gobio*, Gnth., differs greatly from *Pseudaphritis*, and must receive a new generic name. He concludes by suggesting that *Eleginus bursinus*, C. and V., is identical with *P. urvillii*, in which case our species would have to be called *Pseudaphritis bursinus*.—Notes on the species of *Cypræa* inhabiting the shores of Tasmania, by C. E. Beddome.

AMSTERDAM.

Royal Academy of Sciences, September 25.—Prof. van de Sande Bakhuyzen in the chair.—Mr. Hoek on the results of an inquiry, made by order of Government, into the practice of fishing with so-called "ankerkuilen" (large tow-nets not unlike those employed in the Thames estuary for the whitebait-fishing), used in close time (April 1–June 15), in the mouth of the river, just below the limit of the farmed-out part, particularly with regard to our knowledge of the habits of the salmon, its migrations, &c.—Prof. Suringar presented a fifth contribution to the knowledge of the Melocacti, as a sequel to previous papers. The author showed the skeleton and a photograph of a specimen of *Melocactus humili* from Venezuela, described by himself in 1889, and seeds of which he sent at the time to the firm of Damman and Co., near Naples. It seems that the culture of this plant, which does not succeed in hothouses in North and Middle Europe, might be tried with advantage in the sunny climate of the South Italian coast, exposed to sea-winds. Prof. Suringar exhibited a live specimen, now seven years old, raised from the seed by the above firm, and which has already blossomed and borne fruit. With the exception of a slight difference in size and shape, the mother- and the daughter-plant are very similar. In the colony itself, too, the culture will be tried, that it may be possible to send culturable specimens over from there without detriment to the natural flora. The author exhibited photographs and gave a description of five new genera, received from Curaçao. The berries of these specimens, which have developed themselves on the plants in tolerably large numbers after the arrival of the latter, will be sent back to the colony, together with those of some known genera, received at the same time and determined in Amsterdam, to be sown there, so that the seedlings will at once go by their right names. In conclusion the author presented for inspection the first part of the Iconography announced some time back and published by the firm of E. J. Brill at Leyden, as the third volume of the "Musée Botanique" and entitled "Illustrations de Melocactus," with reproductions of photographs and coloured plates of the thorns, flowers and fruits.—Prof. Lorentz on the partial polarisation of the light emitted by a source in a magnetic field. The author showed how this phenomenon (discovered by Egoroff and Gorgiewsky) may be explained by taking into account the absorption which the rays of one part of the flame undergo in the other, this absorption being modified when the periods of the vibrations are changed by the Zeeman effect. In support of this view the author described an experiment in which the light of a sodium-flame which is placed outside the field, is found to be partially polarised after it has passed through a similar flame standing between the poles.—Prof. van der Waals on the graphic representation of equilibriums by means of the ζ-function. The author observed that at a given pressure and temperature, ζ has three values, and that consequently in general a surface is obtained, consisting of three sheets. Coexisting equilibriums exist if a common tangent plane to points either of the same sheet or of different sheets is possible. Increased pressure causes the heterogeneous region to decrease if the mixing is accompanied by contraction, and conversely. Similarly a rise of temperature causes the heterogeneous region to decrease if a supply of heat is required for the mixing, and conversely.—Prof. Behrens read a paper on mixture crystals of $KMnO_4$ with $KClO_4$ and of Ag_2CrO_4 with Ag_2SO_4, which may serve to prove the presence of perchloric and chromic acid. That these crystals are not discoloured by saturated solutions of $KClO_4$ and of Ag_2SO_4, must not be explained by assuming the crystals to be impenetrable, as enclosures are dissolved under similar circumstances.—Prof. Behrens also dealt with micro-reactions of free sulphuric acid, free ammonia and free alkalis. The first is owing to the formation of quinineherapatheite, the second to the formation of palladoammonium chloride. To detect KOH and NaOH together, the solubility of $PbCrO_4$ in caustic alkalis may be made use of; if they are to be separated at the same time, niobic acid hydrate is the best reagent. With KOH it yields a transparent solution, with NaOH colourless needles and rods. Antimonic acid hydrate too easily forms difficultly soluble salts with KOH.—Prof. Martin read a paper on the geology of the Moluccas, in connection with a work published by himself, supported by Government, and entitled "Reisen in den Molukken, in Ambon, den Uliassern, Seran (Ceram) und Buru, Geologischer Teil." A large portion of Ambon is of volcanic origin, and contains the continuation of the chain of volcanoes in Halmahera; Wawani in Ambon had an eruption as late as 1674. On the other hand, Wallace's opinion that Buru and the north-western part of Seran (Ceram) are volcanic, is incorrect. The author ascribed the eruptions in Halmahera, Ternate and Ambon to lateral displacements in the earth's crust, for in the most recent geological part terrific elevations took place; in Ambon, for instance, the new reef chalks are situated as high as 480 m. above the sea-level. Volcanic eruptions and elevations are evidently intimately connected in those regions.—Prof. van der Waals presented on behalf of Dr. D. F. Tollenaar, for publication in the *Proceedings*, a paper on "Deflection and reflection with two kathodes." The phenomena occurring when two kathodes are used, and which were described in a previous paper, may be explained in a simple way if the kathode rays are assumed to consist of negatively-charged particles, which are emitted with great velocity Adopting Schuster's formula for the potential fall in the proximity of a kathode, the course of such a particle, near a kathode, can be calculated. In this way the following results are arrived at: (1) behind the deflecting kathode the kathode rays cut each other, and so give rise to a surrounding sheet of light; (2) if the two kathodes emit their rays towards each other, then the rays of one kathode are partly so strongly deflected by those of the other as to be reflected to the emitting kathode; (3) with each of the two kathodes these reflected rays give rise to a second enclosing sheet of light and a corresponding deflection figure; (4) if the two kathodes are made to be of different intensity, the sheet of deflection formed by these reflected rays becomes larger towards the less intense kathode. This sheet of deflection, however, is not an ordinary Goldstein macro-surface, but might be called a pseudo macro-surface.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 25.

ROYAL SOCIETY, at 4.30.—On the Geometrical Treatment of the "Normal Curve" of Statistics, with especial reference to Correlation, and to the Theory of Error: W. F. Sheppard.—Mathematical Contributions to the Theory of Evolution. IV. On the Probable Errors of Frequency Constants, and on the Influence of Random Selection on Variation and Correlation: Prof. K. Pearson, F.R.S., and L. N. G. Filon—On Certain Natural Media for the Cultivation of the Bacillus of Tubercle: Dr. A. Ransome, F.R.S.—Further Note on the Transplantation and Growth of Mammalian Ova within a Uterine Foster-mother: Walter Heape.—Further Observations upon the Comparative Physiology of the Suprarenal Capsules: Swale Vincent.—Summary of Prof. Edgeworth David's Preliminary Report on the Boring at Funafuti: Prof. T. G. Bonney, F.R.S.—On the Determination of the Indices of Refraction of Various Substances for the Electric Ray. II. Index of Refraction of Glass: Prof. J. C. Bose.—On the Influence of the Thickness of Air-Space on Total Reflection of Electric Radiation: Prof. J. C. Bose.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Accumulator Traction on Rails and Ordinary Roads: L. Epstein. (Continuation of Discussion.)

CAMERA CLUB, at 8.15.—Photographic Action writ large: a Kurveylinear Conversation on Corn: Prof. Armstrong, F.R.S.

LONDON INSTITUTON, at 6.—Acetylene: Prof. Vivian Lewes.

FRIDAY, NOVEMBER 26.

PHYSICAL SOCIETY, at 5.—Upon the Failure of German Silver and Platinoid Wires: Rollo Appleyard.

SATURDAY, NOVEMBER 27.

ESSEX FIELD CLUB (at Buckhurst Hill), at 7.—The Entomostraca of Epping Forest: D. J. Scourfield.—Report on Conference of Delegates of Corresponding Societies at Toronto: Prof. R. Meldola, F.R.S.

MONDAY, NOVEMBER 29.

SOCIETY OF ARTS, at 8.—Gutta-Percha: Dr. Eugene F. A. Obach.

IMPERIAL INSTITUTE, at 8.30.—Kafiristan: Sir George S. Robertson.

INSTITUTE OF ACTUARIES, at 5.30.—Address by the President.

TUESDAY, NOVEMBER 30.

ROYAL SOCIETY, at 4.—Anniversary Meeting.

ZOOLOGICAL SOCIETY, at 8.30.—On Regeneration of the Legs in the *Blattidæ*: H. H. Brindley.—On a Gigantic Sea-Perch (*Stereolepis gigas*): G. A. Boulenger, F.R.S.—Description of a New Tortoise of the Genus *Sternothærus*: G. A. Boulenger, F.R.S.—Remarks upon a Mountain Reedbuck from the Eastern Transvaal: F. V. Kirby.

INSTITUTION OF CIVIL ENGINEERS, at 8.—On the Law of Condensation of Steam: Hugh L. Callendar, F.R.S., and John T. Nicolson.

WEDNESDAY, DECEMBER 1.

SOCIETY OF ARTS, at 8.—The American Bicycle—the Theory and Practice of its Making: Dr. Leonard Waldo.

GEOLOGICAL SOCIETY, at 8.—A Revindication of the Llanberis Unconformity: Rev. J. F. Blake.—The Geology of Lambay Island, Co. Dublin: C. I. Gardiner and S. H. Reynolds.

ENTOMOLOGICAL SOCIETY, at 8.

THURSDAY, DECEMBER 2.

LINNEAN SOCIETY, at 8.—On the Anatomy of *Caudina coriacea*: Prof. Arthur Dendy.—On some Desmids from the United States: W. West and G. S. West.——Exhibitions: Specimens of Galls of *Cecidomyia*: Prof. J. B. Farmer.—An Egg of *Echidna*: Martin Woodward.

CHEMICAL SOCIETY, at 8.—Ballot for the Election of Fellows.—On Collie's Space-Formula for Benzene: Dr. F. E. Matthews.

CAMERA CLUB, at 8.15.—Photomicrography: Dr. Spitta.

FRIDAY, DECEMBER 3.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Permanent Way: its Construction and Relaying: Grote Stirling.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Agricultural Chemistry: R. H. Adie and T. B. Wood, 2 vols. (K. Paul).—La Face de la Terre: Prof. E. Suess; traduit E. de Margerie, Tome 1 (Paris, Colin).—Leitfaden für Aquarien- und Terrarienfreunde: Dr. E. Zernecke (Berlin, Schmidt).—Die Moorbrücken im Thal der Sorge auf den Grenze Zwischen Westpreussen und Ostpreussen: H. Conwentz (Danzig, Bertling).—The Story of a Red Deer: Hon. J. W. Fortescue (Macmillan).—The Gallinaceous Game Birds of North America: D. G. Elliot (Suckling).—Practical Forestry: Prof. C. E. Curtis, 2nd edition (Lockwood).—The Hope Reports: edited by Prof. Poulton, Vol. 1 (Oxford).—Recherches Experimentales sur quelques Actinomètres Électrochimiques: Dr. H. Rigollot (Paris, Masson).—La Culture des Mers en Europe: G. TEA.

A Text-Book of Tea Planting and Manufacture. By David Crole. Pp. xii + 242. (London: Crosby Lockwood and Son, 1897.)

THIS handsomely got-up book, although written with too obvious a bias in favour of the produce of India and Ceylon, as distinguished from that of China, is a valuable contribution to the literature of an important subject. Mr. Crole's experience has been mainly gained in the "gardens" and "houses" of Assam, but he has evidently had good opportunities of acquiring information from personal observation of the methods of cultivation and manufacture in other parts of our East Indian possessions. Of China he apparently knows nothing from personal experience, and the value of his strictures on the character of the produce, as well as of the modes of manufacture, of the Celestial Empire may be said to suffer in consequence. The book is mainly written for the benefit of planters, but there is much in it of interest to the general reader who is not insusceptible to the charms of "the sovereign drink of pleasure and of health." The extraordinary growth in the consumption of tea in Great Britain is a significant feature in our social and domestic economy. As it is the fashion just now to compare everything at present with what it was in 1837, it may be interesting to note that whereas in that year the amount of tea consumed in this country did not exceed 30,000,000 lbs, all of which came from China, the quantity now imported is upwards of 230,000,000 lbs., or more than 5⅝ lbs. per head of population. China now furnishes less than half the amount she sent into this country at the time of the Queen's accession. The import from India, which began in the early 'sixties, now amounts to more than five times that from China; whilst Ceylon, which has only sent tea into this country to any extent during the last fifteen years, furnishes us with more than three times the quantity of that from China. In other words, China now sends us only about 10 per cent. of our tea, whereas ten years ago she gave us half the amount we then consumed. It is obvious, therefore, that unless China can be induced to abandon her absurdly exclusive policy, her tea trade with and through this country is doomed.

As is well known, Chinese tea is mainly made from the *Thea chinensis*, whilst that from India is the produce of *T. assamica*. Mr. Crole calls the former variety "a poor, scrubby-looking shrub" and "a wretched plant." From his remarks it would appear that the only service that Fortune rendered to the Indian tea industry by the introduction of the Chinese plant was the deterioration of the indigenous seed, giving rise to quantities of hybrids of various qualities, "from very rank stuff to fairly good." According to the author, the most that can be said in favour of the China plant is that it is distinctly more hardy than the Assam variety. We are disposed to believe that Mr. Crole's prejudices affect his judgment. There is no question whatever that some of the finest and most wholesome tea the world produces is to be met with in China. Whether it is to be met with in this country is wholly a question of price.

Mr. Crole's account of the rise and development of the Indian tea industry forms one of the most interesting chapters in his book, although here, as in the whole work, he never loses an opportunity of casting a slur upon the China tea plant. This he stigmatises as "the pest of Assam," and its introduction a curse "that at one time seemed as if it would prove as disastrous to Assam as ever the *Phylloxera vastatrix* has been to France, or the *Hemileia vastatrix* in Ceylon." No mention is made of Fortune and his labours—which, whatever may have been his merits or demerits, is inexcusable in what purports to be an historical narrative. Full justice, however, is done to Sir Joseph Banks' efforts to introduce the Chinese plant into India as far back as 1793, and to the remarkable and accurate knowledge he showed in his selection of suitable stations for its cultivation. The discovery that a variety of *Thea* was indigenous to Assam has been claimed for a number of persons, but, according to the author, the credit indubitably belongs to Mr. R. Bruce, who first met with the plant on the hills round Rungpore in 1823. The justice of the award for this discovery, subsequently made by the Government to Mr. Bruce, which gave rise to some little controversy at the time, is thus borne witness to.

The chapters on cultivation and manufacture, although perhaps too technical for the ordinary reader, are undoubtedly the most valuable in the work. They are based upon the author's individual experience and upon a comparison of the methods employed in different parts of the various provinces, not only in Assam proper, in Cachar and Sylhet, but also in the Dooars and Darjeeling districts of Bengal, in the Punjab, in Madras and in Ceylon. They are, of course, of special interest to the planter, by whom they will doubtless be studied with the attention they merit. It is, however, noteworthy that certain minor details of manufacture, especially the operation of sorting, as usually conducted, have only served to confirm the author's inherent dislike to the beverage; for he tells us, with a perfect candour, that he never drinks tea by any chance—but rather wishes to be transported, with Pope's Belinda, to some isle where "none e'er drink Bohea."

Perhaps the least satisfactory portions of the book are those relating to the chemistry of tea during growth and manufacture. The subject is no doubt beset with difficulties, and although the author, with the assistance of Prof. Bayne, has evidently done his best, the result compares somewhat unfavourably with the rest of the work. To be told that tea contains organic acids, and that organic acids in their turn "contain the carboxyl group radical (COOH)," which is all the information vouchsafed, is not instructive to the average man, and not worth the telling to the chemist. Nor even if its construction were to be amended, is any precise information to be extracted from the following sentence. "Volatile oils . . . consist of two parts: (1) solid stearopton, and (2) liquid oleopton; all contain decone ($C_{10}H_{16}$), which is a member of the turpene series of hydrocarbons, or some polymer, and are obtained by distillation with water." The author appears to be somewhat sceptical as to the identity of caffeine with theine, and sees in the experiments of Brunton and Cash evidence that the substances are isomeric and not identical. He finds from observations made on himself that coffee is decidedly antidotal to nicotine, whereas tea is not; but he admits that this circumstance does not go far towards proving the essential dissimilarity of the two alkaloids. By nicotine is presumably meant tobacco-smoke, which is by no means the same thing.

Mr. Crole is of opinion that the value of a tea should be in direct proportion to the theine it contains. This is surely no more true than that the value of a wine depends upon its alcoholic strength. Indeed, the author admits that what the consumer likes in tea is strength, body, and delicacy of flavour, and that he does not trouble himself about the theine, of which he has no means of estimating the amount. As a matter of fact, there is absolutely no connection between the commercial value of tea and the quantity of theine which may be present in it.

The last chapter in the book deals with the thorny question of the coolie. The Assam plantations, as well as those of Ceylon, have to depend entirely upon imported labour; but whereas the Ceylon gardens are almost wholly worked by Tamil coolies, who are free labourers, those in Upper Assam are recruited under Government licence, and by means of a system which, it is admitted, is attended with much cruelty and deception. There is, in consequence, considerable disaffection and much disquietude occasionally on the plantations, and the local magistrates are at times greatly exercised to settle the "labour troubles" which now and again break out. Mr. Crole lifts the veil only slightly, but it is sufficiently obvious that when disciplinary duty is to be done, the planter's lot, as well as that of the coolie, is not altogether a happy one. The social life on an Indian tea-garden is, perhaps, not to be judged of from a Western standpoint; but probably nothing exactly resembling a Fagua festival in wanton licence and depravity was ever seen on a Louisiana plantation, even in the best (or worst) of the "good old times."

In spite of occasional grammatical lapses and faults of style, Mr. Crole's book may be recommended as an accurate and fairly impartial account of the present state of the tea industry in our East Indian possessions.

WILD-FOWLING.

A History of Fowling, being an Account of the many Curious Devices by which Wild Birds are or have been Captured in Different Parts of the World. By the Rev. H. A. Macpherson. 8vo. Pp. liv + 511, illustrated. (Edinburgh: Douglas, 1897.)

ALTHOUGH the treatise before us can in no way be regarded as a scientific work, yet the capture of wild birds entails so many accurate observations on the habits and mode of life of the quarry, that such a full account of all that is known on the subject must of necessity throw many interesting side-lights on the study of ornithology proper. And no lover of birds will fail to find much matter worthy of his attention in Mr. Macpherson's handsome and well illustrated volume. The author appears to have spared no pains in collecting material for his history, and he has been fortunate in finding correspondents in all parts of the world who have supplied materials relating to their own particular countries which probably could not have been obtained from any other sources. Indeed, the work largely consists of extracts from the letters and publications of such correspondents, the source of which is, however, fully acknowledged both in the preface and in the text.

The work practically has the field to itself, and is long likely to remain the standard authority on the subject. The number of types of curious instruments for the ensnaring of birds Mr. Macpherson has succeeded in recording is astonishing, and speaks well for his own industry, and the interest that has been taken in the subject by his numerous correspondents. Perhaps the most remarkable of all is a snare employed in Borneo and Tenasserim for the ensnaring of the lovely Argus Pheasant. This bird, as is well known, exhibits a peculiar intolerance to the presence of any foreign object which interferes with free progress over its favourite playground. Taking advantage of this trait, the natives fix on the playground a couple of sharp bamboo knives tied together in the form of an inverted V, with their sharp edges downwards. Finding the knives thus fixed on its own particular territory, the Argus endeavours to remove them by twisting its neck round one of the blades from beneath, and, in the course of its efforts to overturn them, eventually manages to cut its own throat. In connection with this passage, it may be mentioned that the word "Argus" is omitted from the index, although it is mentioned under the heading "Pheasant."

Some limitations have necessarily had to be imposed on the extent of the subject, which might well have included punt-shooting and hawking, if not ordinary covert-shooting and driving. For since the author includes the blow-pipe and the bow-and-arrow among the engines of destruction used in fowling, there is no logical reason for the exclusion of the punt-gun and the shot-gun. But as treatises on shooting exist by the score, while hawking has also numerous works devoted to its mysteries, the author seems to have exercised a wise discretion in the limits he has laid down. And even as it is, the work extends to a very considerable bulk, although there are not a few portions where considerable abridgement would have been no disadvantage.

The author divides the implements employed in fowling into four main classes. Firstly, weapons of attack, such as the blow-pipe, the bolas, and the bumerang; secondly, the stalking-horse, or some analogous method for approaching the game without being seen; thirdly, birdlime; and fourthly, the various kinds of snares and traps, including decoys, nets, gins, &c. Having cursorily glanced at the leading types of these, Mr. Macpherson next gives a classified list of the birds treated of, and then in the text proceeds to dilate upon the particular method of capturing the members of each group or species. It is in regard to the snaring of the smaller birds that condensation might have been advantageously resorted to, as numbers of these might perfectly well have been treated *en bloc*, instead of having separate sections devoted to them, which are only too likely to weary the great majority of readers. Indeed, from the point of view of the present reviewer, the work would have been doubled in value had it been diminished by at least one half in bulk.

Passing by these long chapters devoted to the smaller birds, more general interest will be found in the section on hawk-catching, as this is a subject on which comparatively little is often found in works on hawking; and it is decidedly interesting to know how the captors are themselves taken. We have descriptions of the capture of the Peregrine in our own islands, of the Gyrfalcon in Iceland, the Shahin in India, and many other species in different parts of the world. After full descriptions of the capture of swans and geese, several very interesting chapters are devoted to the taking of the various kinds of ducks, in the course of which driving and spearing, snaring, the different types of decoys, and clap-nets, receive their full meed of attention. The information in regard to decoying in Europe may, for the most part at any rate, be found in other works, but much of that relating to Japan and other Oriental countries appears to be new to English readers. The Japanese are described as peculiarly dexterous in the use of an ingenious collapsible triangular hand-net, in which they take the birds already enticed into the pipe of the decoy. They have three favourite methods of using this ingenious and handy instrument. The first is to spoon the duck into the net as the bird is swimming; the second, to capture the bird as it rises from the water in the pipe; while the third feat is to hurl the instrument at a duck flying out of reach, and bring it to the ground entangled in the meshes. In the course of one of these chapters on duck-catching, the shot-gun is for once introduced, in connection with a method of attracting the wily birds within range by means of a brilliant light and reflector. Another peculiarly Japanese method is to fish for ducks with a hook and line.

Numerous and various are the methods employed for trapping and decoying the various kinds of pigeons and game-birds, but, interesting as many of them are, they must be passed without notice. The last chapter relates to the ostriches and their kindred, in which we have accounts of African, Patagonian, and Australian hunting. Here the author is doubtless right in his statement that the Arabs used to kill ostriches by disguising themselves in the skin and feathers of one of these birds; but was not the same method in use among the Bushmen of the Cape?

In the matter of letterpress and illustrations the book is for the most part all that can be desired; and it can scarcely fail to claim a wide circle of readers. R. L.

OUR BOOK SHELF.

Life Histories of American Insects. By C. M. Weed, D.Sc., Professor of Zoology and Entomology, New Hampshire College. Pp. xii + 272. Woodcuts. (New York: The Macmillan Co. London: Macmillan and Co., Ltd., 1897.)

WE opened this book with lively expectations of something good. Though there has been considerable activity among American entomologists during the last ten years, our knowledge of the life histories of American insects is still very defective, and there is urgent need of more labourers, especially of such as bend their minds to the solution of really important questions. Not only the title of the book, but the printing and the figures are attractive, and we began the first chapter with high hopes, only to draw a blank. The author had nothing particular to say about Belostoma. Chauliodes came next—nothing of the slightest importance here. Then came the tiger-beetles and their larvæ—again nothing new. The rest of the book is of the same slight texture. Nothing is worked out with any completeness; we have merely scraps of information, mostly from printed sources. The author's use of books is uncritical. Thus Dr. Le Conte is quoted for the explanation of the leaping of the click-beetle, and Prof. Comstock for the description of the sonorous file of the cricket, though these authors did not discover the facts for which they are cited. Let us hope that Prof. Weed or some one else will before long give us a book which is really entitled to bear the name of "Life Histories of American Insects." L. C. M.

The Röntgen Rays in Medical Work. By David Walsh, M.D. With an introductory section by J. E. Greenhill. Pp. x + 144. (London: Baillière, Tindall, and Cox, 1897.)

THIS book, as is intended, will be of interest chiefly to the medical profession. The introductory part, which deals briefly though clearly with the practical and physical side of the subject, will also be found useful by those who desire to employ X-rays for other purposes.

The book is methodically arranged, well got up, and is illustrated with a large number of remarkable and excellent specimens of X-ray photography, mostly of anatomical interest.

Altogether it contains good evidence of the real value of X-rays in practical surgery and medicine, especially the former, and of the rapid progress that their employment has made in their application to these important fields.

It is interesting to note that while the author is fully cognisant of the powerful effects that X-rays under certain circumstances may produce upon the skins of particular individuals, he is satisfied that, so far as present experience goes, they have no particular action upon micro-organisms.

The introduction is somewhat misleading where it states, on p. 23, that the action of the induction coil depends upon the fact discovered by Faraday, that an electrified body is capable of inducing a similar condition in an unelectrified body lying within the sphere of its influence. It was electro-magnetic, and not electrostatic induction which Faraday discovered, and it is owing to the former, and not to the latter phenomenon that the induction coil is possible. Again, there is another slip on p. 26, where it is mentioned that kathode rays can be reflected, refracted, polarised, and deflected by a magnet just as ordinary light. Kathode rays, of course, have never been refracted or polarised, and ordinary light is not deflected by a magnet.

Air, Food and Exercises; an Essay on the Predisposing Causes of Disease. By A. Rabagliati, M.A., M.D., F.R.C.S.Ed. Pp. xvi + 220. (London: Baillière, Tindall, and Cox.)

THE book under review is an amplification of papers contributed to the *Scalpel* during the year 1896. The main proposition elucidated in the essay may, in the words of the author, be said to be this: "that there are three predisposing causes of disease, as there are, conversely, three chief predisposing causes of health, and that these are air, food and exercises." In the course of his essay, the writer gives his opinion on the subject of heredity, which, he thinks, "counts for very little as a predisposing cause of disease and of health, among adults at least, if not even among persons who have passed the tender years of early childhood." Heredity is indeed spoken of somewhat contemptuously in the book, and, bracketed with germs, is described as a fetish, "so blindly and superstitiously is it invoked." In the opinion of the author, five per cent. would be a fairer estimate for the hereditary diseases incident to adult humanity than even ten—an estimate previously conceded in the course of the argument. The book is not written for the practitioner, by whom, in fact, many of the opinions and views of the author might be challenged, but for the lay- man and woman, who will find in it many hints as to the diet and physical exercise of the body, which may be calculated to make easier the task of keeping the body in a state of health. Being intended for the perusal of the non-professional reader, the work throughout is written in a style which will be easily understood by all.

Elementary Drawing: a Series of Practical Papers for Beginners. Written and illustrated by Elisabeth Moore Hallowell. Pp. 54. (London: Macmillan and Co., Ltd., 1897.)

AT first sight the scope of this small book does not seem to fall within the area covered by the columns of NATURE, the series of papers of which the work is composed having originally been written for the *Art Amateur*, "to give to beginners in drawing a simple explanation of some matters usually considered too elementary for text-books"; yet it will be owned by all that a knowledge of drawing is, if not absolutely necessary, very useful to the student of science in whatsoever branch he may be engaged, and thus a brief notice of the volume may not be out of place here. The book, although written in easy language, is not intended for very young readers, but "for those who are able to follow from one lesson to another, up to the point where the present volume ends and the general text-book begins." It will, we should think, be found very acceptable to many who have not had the advantage of early training in art, but who wish to gain some idea of its principles; and especially useful will it be to those to whom attendance at a drawing class is impracticable. A careful student of this unpretentious volume will be in possession of some very useful hints, and will have acquired knowledge which will stand him in good stead in his after studies.

Botanisches Bilderbuch für Jung und Alt. By Franz Bley. Part i. With explanatory text by H. Berdrow. Pp. 96. Plates 24. (Berlin: Gustav Schmidt, 1897.)

THE best way to obtain a knowledge of common flowers is to go into the woods and meadows with an outdoor botanist. Unfortunately, a naturalist cannot always be found able and willing to impart the required information, and the most satisfactory substitute in such cases is a collection of coloured pictures (uncoloured pictures are useless for purposes of identification) of flowering plants commonly seen. We have several works of this kind in our own language, a very good one being Mr. Edward Step's "Wayside and Woodland Blossoms." The volume before us is similar in character, though not so handy in size as Mr. Step's. There are 216 coloured figures of plants on twenty-four plates, and brief descriptions of each species represented. The species described and illustrated are those which flower in the first half of the year, and they are arranged according to the succession of the months. Another volume will be published for flowers of the second half-year. The figures are mostly very good, and the text has been designed to interest the reader in plant life and functions. The plant-lore referred to in the descriptions of many of the species will assist in popularising the book and making it acceptable to young students of botany in Germany.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Volcanic Condition of Stromboli.

IN view of the fact that all published accounts of Stromboli, according to the *résumé* given by Bergeat ("Der Stromboli," A. Bergeat, Habilitationschrift, München, 1896), have agreed in describing the volcano as being explosively active, there may some interest attach to a statement of the present condition of affairs, as seen by Prof. H. F. Reid, of Johns Hopkins University, and the writer, on October 27 and 28 of the present year. The westernmost of the four small craters described by Bergeat was not observed at all, the next two were discharging rather copious volumes of vapour, and the easternmost, or "old," crater was giving out a very little steam from its bottom. The most steam was issuing from cracks in the eastern rim of the "old" crater, especially from one at the north-eastern or seaward corner of the rim. Much steam was issuing from the southern rim overhanging the second and third craters and the ridge leading from it to the main mountain mass. Nothing in the nature of an eruption was taking place, and it was evident that the craters had been in this condition for some time. Later inquiry at Lipari elicited the information from Bartolo Nicotera, the guide, that there had been no eruption on Stromboli for about a year. The high ridge over the crater, known as the Cima, showed steam issuing from along its summit, more than 200 metres above the crater. E. O. HOVEY.

Naples, November 26.

The Colours of Flowers Blooming Out of Season.

I HARDLY think it probable that you will be able to spare your valuable space for my communication; nevertheless, I venture to send you the following observations on the tendency of flowers to revert in colour when blooming out of season. We have had little frost here, and many flowers which are ordinarily out of bloom at this season still persist. The changes, however, in their normal colours are in some cases very remarkable. The red cactus dahlias are blooming almost orange, the outer florets being often nearly yellow. These dahlias are also, in many cases, showing a tendency to revert to the single form. A species of tropeolum, normally vivid scarlet, is blooming in a cool greenhouse, where air is kept on, and has in some cases reverted almost to clear yellow; a streak of red down the centre of the petal being the only remains of its normal colour. In both the above cases I note that the edges of the petals are the first to change. A species of myosotis, ordinarily of a deep and very vivid blue, is flowering now a clear rosy pink, without the least tinge of blue. The flowers are well opened and normal in size. Lastly, a pure white phlox of dwarf habit shows a tendency to revert in some of its blooms, though not in all, to a greenish yellow hue. Such cases are probably common; but it is with the feeling that they may point to climatic conditions as influencing the coloration of flowers, and as having, possibly, borne a large part in the gradual evolution of their respective tints, that I venture to record them. E. HUGHES-GIBB.

The Manor House, Tarrant Gunville,
Blandford, November 20.

A Rose-Coloured Rainbow.

ON page 263 of Lord Tennyson's "Memoirs" there is mention of a "red rainbow" seen at sunset in 1882. As it was considered noteworthy by Sir Norman Lockyer, and was the first he had heard of, it may be of interest respecting sunset phenomena that near Hayward's Heath, on June 29 of this year, at sunset there was a rainbow entirely of a clear rose-pink against heavy storm clouds over half the sky, and facing a deep golden sunset in a clear sky. It was a perfect arch, and lasted for some minutes. Just for a moment I saw a streak of pale sea-green in the midst of the rose colour. M. S. ZACHARY.

Holy Cross Home, Hayward's Heath.

Critical Temperature of Water.

In answer to Mr. Martin's letter in your last issue (p. 80), Cailletet and Colardeau found the critical temperature of water to be 365° C., the corresponding pressure being 200·5 atmos. An account of their experiments is given in Preston's "Theory of Heat," p. 384.

S. GEOGHEGAN.

Dublin, November 29.

SPECTRUM OF A METEOR.[1]

The photographs of the spectra of the stars taken at the Harvard College Observatory as part of the Henry Draper Memorial differ in two respects from those ordinarily taken elsewhere. Instead of using a spectroscope with a slit, in which but one star is photographed at a time, a large prism is placed over the object-glass of the telescope, and thus spectra of all the bright stars in the field of view are obtained. The number of stars photographed simultaneously is still further increased by substituting for the object-glass a portrait lens like that used by photographers, only larger. The field of view is in this way increased from two degrees square to ten degrees square, and a photograph is obtained of the spectra of all the brighter stars in this large region. Many thousand plates, covering the entire sky, have been taken in this way at the Cambridge and Arequipa Stations of this Observatory. All have been examined by Mrs. Fleming, and, as a result, numerous remarkable objects have been discovered. One of the latest is the spectrum of a meteor which has thus been photographed for the first time. Since it is impossible to foresee when the bright meteors will appear, or what path they will follow, a photograph will be obtained only when one happens to cross the field of the telescope. A number of trails of meteors have been obtained, both here and elsewhere, when charts of the stars were photographed, no prism being used. When the prism was in place no meteor bright enough to leave a noticeable trail has heretofore been photographed on the many thousand plates examined. At about 11 p.m. on June 18, 1897, however, when the 8-inch Bache telescope at Arequipa was directed towards the constellation Telescopium, a bright meteor appeared in right ascension 18h. 19m., declination −47° 10′, and passed out of the field at right ascension 18h. 29m., declination −50° 30′. The spectrum consists of six bright lines whose intensity varies in different portions of the photograph, thereby showing that the light of the meteor changed as its image passed across the plate. The approximate wave-lengths of these lines are 3954, 4121, 4195, 4344, 4636, and 4857, and their intensities are estimated as 40, 100, 2, 13, 10, and 10, respectively. The first, second, fourth, and sixth of these lines are probably identical with the hydrogen lines $H\epsilon$, $H\delta$, $H\gamma$, and $H\beta$, whose wave-lengths are 3970, 4101, 4341, and 4862. The fifth line is probably identical with the band at wave-length 4633, present in spectra of stars of the fifth type and forming the distinctive feature of the third class of these stars. The third line, which is barely visible, is perhaps identical with the band at wave-length 4200, contained in these stars (*Astron. Nach.* 127, p. 1).

It will be noticed that of the four hydrogen lines in the spectrum of the meteor, $H\delta$ is the most intense. This is also the case in the spectrum of o Ceti and of many other variable stars of long period. In some variables of long period $H\delta$ and $H\gamma$ are equally intense, while in others $H\gamma$ is the more intense. In some stars of the first type in which the hydrogen lines are bright, like γ Cassiopeiæ, the line $H\beta$ is much more intense in the photographic spectrum than any of the other lines, while in the spectra of stars like P Cygni and η Carinæ, $H\delta$, $H\gamma$, and $H\beta$ are nearly equally bright. These results show an important resemblance between meteors and stars having bright lines in their spectra, and may aid in determining the conditions of temperature and pressure in these bodies. Since bright meteors sometimes appear during the November meteoric shower, a special effort will be made to obtain photographs of them, both trails and spectra, on November 13.

November 8.

EDWARD C. PICKERING.

GEOLOGY AND SANITARY SCIENCE.

The address recently delivered by Mr. W. Whitaker, F.R.S., before Section iii. of the Congress of the Sanitary Institute (*Journal of the Sanitary Institute*, vol. xviii., 1897, pp. 304–316), touches upon several matters of special interest at the present time. Section iii. deals with chemistry, meteorology, and geology, and Mr. Whitaker chose for his subject "Water," as being appropriate for such a triple alliance. Most important is his suggestion "that round each work for the public supply of water a certain tract of the water-bearing bed should be saved from the assaults of surface-contamination." The address was delivered before the Maidstone epidemic had occurred, but reference is made to it in a postcript, and no stronger support for Mr. Whitaker's proposal could have been given. He rightly observes that "we are yet without much information as to how far pollution may be able to reach along an underground course," but "it is here that geology comes in, for the nature of the surroundings of waterworks must be taken into account, often for some distance and to some depth." From a sanitary point of view the mapping of all the surface deposits on the six-inch scale by the Geological Survey is referred to as most necessary. A great deal has been done, but very much more remains to be done; and, as Mr. Whitaker observes, "a survey of the drifts in the London area on the six-inch scale is greatly needed."

It is a serious matter when sewage-farms and cemeteries are placed on porous strata, which are perhaps in adjacent tracts utilised for their supply of water; and yet, as Mr. Whitaker remarks, "sewage-farms and cemeteries must exist, until some other methods of disposing of waste material are not only found out, but are generally adopted."

Clearly there is need for greater control over the sites chosen for any of the purposes mentioned, and public sources of water-supply must be carefully safeguarded. The question of federation in the matter of water-supply in many localities is one to which attention is drawn, and this also is becoming urgent.

NOTES.

The French Government, through its Embassy in London, has presented to Sir Archibald Geikie a handsome vase of Sèvres porcelain in recognition of the services rendered by him to the Geological Survey of France.

We are pleased to hear of the foundation of the Zoological Society of Western Australia, with the object of establishing a Zoological Garden at South Perth in that colony. Mr. E. A. Le Souef has been appointed director of the new institution.

It is announced that the Council of the Iron and Steel Institute have accepted an invitation from the Association of Swedish Ironmasters to hold the autumn meeting of the Institute next year at Stockholm. The meeting will be held in August, and, in view of the large quantities of Swedish iron and ores consumed in this country, there is no doubt that it will prove a very popular meeting. Previous autumn meetings of the Institute have been held at Belgium, France, Germany, Austria-Hungary, Spain, and the United States.

A BUST of Pasteur was unveiled at Melun on Monday as a memorial of his investigations on anti-anthrax serum.

THE death is announced of Dr. Harrison Allen, Emeritus Professor of Comparative Anatomy in the University of Pennsylvania.

THE Allahabad *Pioneer Mail* states that the Röntgen rays are proving of the greatest assistance in dealing with the gun-shot wounds among the troops engaged on the frontier.

THE Bradshaw lecture, in connection with the Royal College of Surgeons. England, will be delivered on Wednesday, December 8, by Mr. Alfred Willett, who will take as his subject the "Correction of certain deformities by operative measures upon bones."

THE New York Zoological Society is making headway in its undertaking to convert a portion of South Bronx Park into the largest zoological garden in the world. It has the right to use the ground; it has the plans for the chief structures to be erected; it has part of the money; and it believes that the public-spirited citizens of New York will contribute the remainder of the funds necessary. In the second number of the new bulletin issued by the Society, we read: "The Society does not propose that any feature of its work shall be performed on a small or cheap scale. The Greater New York should not plan a mere menagerie on the matchless site set aside as a Zoological Park. The Society is carefully studying in this country and abroad what constitutes an ideal vivarium, and it proposes to build one worthy of a great city, or none!" As already announced, the City of New York will provide 125,000 dollars to meet the cost of preparing South Bronx Park for the reception of the Society's costly buildings and collections, and making them accessible to the public, as soon as the Society's improvement fund reaches 100,000 dollars.

AT the Royal Geographical Society on December 6, Lieutenant Peary will give an account of his Arctic work. On December 13, Colonel H. W. Feilden will read a paper on recent visits by Mr. Pearson and himself to the Barents and Kara Seas and Novaya Zemlya. Mr. F. G. Jackson and Mr. Arnold Pike will also speak of their observations on the open Polar Sea of the past summer. On Friday, January 7, and Monday, January 10, at 4 p.m., two Lectures to Young People will be given by Dr. H. R. Mill; the subject being: "A Geographical Holiday through Forest, Prairie and Mountain." The lectures will be illustrated by many photographic lantern slides.

IT is proposed to erect a monument of grey granite, twenty-three feet high, over the grave of Baron von Mueller in St. Kilda Cemetery, and donations are invited for that purpose by the late investigator's executors. Botanists will be pleased to know that the Baron's supplemental volume of the "Flora Australiensis," upon which he had worked for years and was preparing for the press at the time of his death, together with two volumes on his administration as Director of the Botanical Gardens, embracing a biography and complete bibliography of his writings, are to be published. His executors will feel favoured by the loan of any of his letters, or the communication of incidents in the Baron's life which his friends deem to be worthy of notice in his biography. Subscriptions for the monument, or material for the biography, should be sent to the Rev. W. Potter, "Vonmueller," Arnold Street, South Yarra, Victoria.

THE annual dinner of the Institution of Electrical Engineers was held on Wednesday in last week, and was attended by more than two hundred members and friends. In proposing the toast of "The Scientific Societies," Prof. Ayrton compared the conditions of physical research thirty years ago with the laboratories of to-day. Lord Kelvin responded on behalf of the Royal Society, and pointed out the assistance given by that scientific Society to the advancement of natural knowledge. Sir J. Wolfe Barry replied for the Institution of Civil Engineers, and Sir James Crichton Browne on behalf of the Royal Institution. Prof. S. P. Thompson proposed the toast of "Our Guests," and the Marquis of Tweeddale and Dr. Collins (Chairman of the London County Council) replied to it. Sir Courtenay Boyle, in proposing the toast of "The Institution of Electrical Engineers," mentioned that the Board of Trade had already made 256 provisional orders for electric lighting: he hoped that electric traction would soon develop in this country. The President, Sir Henry Mance, replied to the toast, and gave a brief survey of the work of the Institution.

THE autumn meeting of the U.S. National Academy of Science was recently held at Boston. Miss Alice Bates Gould, daughter of the late Prof. B. A. Gould, who was one of the founders of the Academy, presented the sum of twenty thousand dollars, to be known as the Gould Memorial Fund, the income to be used for astronomical and mathematical purposes.—The Academy visited the Jeffersonian Laboratory at Harvard, by invitation of Prof. John Trowbridge of the Scientific School. Prof. Trowbridge exhibited his new X-ray machine. It has a voltage of 1,200,000, and with it are used 10,000 cells and 60 condensers. The condensers are charged in parallel and discharged in series by a movable framework. The spark is 48 inches long.—On the last day of the meeting, Prof. O. C. Marsh made a further contribution to the subject of the Jurassic formation of the Atlantic coast, which he has been investigating for several years. Prof. A. E. Merrill described the effects of tropical seas upon certain animals. Prof. Charles R. Cross explained experiments made by him on the wave siren for determining the pitch of musical sounds. Prof. Seth C. Chandler made a further contribution on the motion of the earth's pole. His experiments, continued for many years, warrant the statement that the area traversed by the pole does not exceed twenty feet in radius. He exhibited charts showing the varying position of the pole for seven years. Major J. W. Powell presented an hypothesis to account for movements in the crust of the earth.—After the adjournment of the meeting, members of the Academy visited the Harvard Observatory under the charge of Prof. Edward C. Pickering, and examined the apparatus and the collection of nearly 200,000 photographs of the heavens which have been made during a period of several years.—The spring meeting of the Academy will be held at Washington on April 19, 1898.

THE reports issued by the Meteorological Office on Saturday last showed that an abrupt change of the conditions of high barometric pressure, which had prevailed more or less persistently for some time past, was taking place; the wind had become more generally south-westerly, and a rise of more than 20° had taken place in the temperature, in parts of England, since the previous day. The fall of the barometer was very rapid, and by Sunday the whole type of weather had thoroughly changed; a large and important cyclonic disturbance had arrived from the Atlantic, and the centre of the storm on Sunday morning lay over the north of Scotland. South-westerly and westerly gales were blowing in most parts of our islands during Sunday, and the barometer near the centre of the storm was becoming still lower as the disturbance advanced. By 8h. a.m. on Monday the centre had travelled in a south-easterly direction across the North Sea to Denmark, causing terrific seas and northerly gales on our eastern and south-eastern coasts. The unusual track followed by the storm was probably owing to the barrier offered by the relatively higher barometric area extending over Scandinavia, while its fury was augmented by an area of high barometric pressure advancing in the rear of the storm, from the Atlantic, and thus increasing the steepness of the barometric gradients over our islands. Much damage has been wrought on our coasts by the violence of both the wind and sea, and now that the high barometric area has been displaced from over this country, further atmospheric disturbances are likely soon to reach us from the westward.

AN example of the reticulated python (*Python reticulatus*), the largest snake that has been in the Zoological Society's reptile-house for many years, and, so far as is known, the largest that has ever been there, died in the Gardens on November 14 last. It measured just over 20 feet in length. This snake was obtained in Malacca, and presented to the Society by Dr. Hampshire on August 29, 1876, and had, therefore, lived rather more than twenty years in this country. During this period it has been fed principally with ducks, of which it sometimes swallowed four or five at one meal. Its food was offered to it once a week, but it sometimes refused to eat for a month together. The specimen will be mounted for the Tring Museum. The largest snake now remaining alive in the Zoological Society's collection is a female Indian python (*Python molurus*), which measures about 18 feet in length. It was obtained by purchase in October 1889.

THE forthcoming annual report to the U.S. Congress of the Secretary of the Interior (Mr. Cornelius N. Bliss), contains much interesting information and many valuable suggestions in renard to Alaska, for which territory a government is contemplated adapted to its rapid development. In the report of the Governor of the territory, Mr. John G. Brady gives a summary of events which have transpired there during the last thirty years. He attaches great importance to the introduction of the reindeer by the Government as an important step in the solution of problems of food supply and transportation. A journey of over 2000 miles, taken with reindeer last winter by the Superintendent of the Government Reindeer Station and two Lapps, shows how well adapted this animal is to the necessities of the people there. It has this great advantage over dogs, that it can feed on the moss which grows everywhere, whereas food has to be transported for the dogs. The report states that, with care, grasses and other staple crops can be cultivated. The whole coast of Alaska, including the islands clear to the eastern end of Kadiak Island, is covered with timber of great value. Statistics regarding pelagic sealing are given, and the branding of all female pups is commended.

A WINTER weather record from the Klondike region is given by Mr. E. W. Nelson in the *National Geographic Magazine* (November). The record was obtained in the autumn and winter of the years 1880-81, at a fur-trading station on the Upper Yukon, not far from Dawson City. It covers the period from the early autumn to the opening of navigation on the Upper Yukon in spring, and is of peculiar interest at present, as showing some of the meteorological conditions in the area which is now attracting world-wide attention. The Yukon froze over on November 2, and was covered with a practically unbroken sheet of ice for more than six months. The temperature sank steadily from the end of October, and in December the lowest temperature, −67° Fahr., was noted The lowest temperatures reached in January, February, and March were −41°, −58°, and −43° respectively. In the last-named month the effect of the returning sun became evident, the greatest range (88°) being obtained during that month. Not until the middle of May, however, did the ice start on the river, and it was some weeks before the river was free enough from floating ice to permit navigation.

IN the *Engineer* of November 19 there is an article upon the measurement of the velocity and pressure of the wind, with illustrations of the various parts of Dines' pressure tube anemometer and of its records. Some years ago the Royal Meteorological Society appointed a committee to consider the subject of wind force, of which Mr. W. H. Dines was a member; he took great interest in the subject and carried out an exhaustive series of experiments, the chief expense of which was borne by the Meteorological Council, who were fully aware of the importance of the subject. The experiments modified to a considerable extent the values of the results obtained by the principal anemometers then in use, viz. the Robinson cup anemometer and the pressure-plate anemometer, and ultimately led to the invention by Mr. Dines of the instrument which bears his name. It consists of two independent parts, the head, with vane, which is exposed to the wind, and the recording apparatus, which may be put in any convenient, sheltered place, at a considerable distance away. These two parts are connected by means of flexible metal tubes, and the arrangement obviates the great difficulty experienced where a mechanical connection has to be maintained between them, as in the case of the two instruments above mentioned, which can never be placed far above a building. The Dines' instrument possesses many advantages over the cup and pressure-plate anemometers, and is much cheaper, while its records combine the characteristic features of both. It is now in action at many stations both in this country and abroad, and will, no doubt, throw considerable light on questions about which there has hitherto been much uncertainty.

THE last number of the *Annales de l'Institut Pasteur* contains the report for the past year of the work carried out at the Station Pasteur de Tiflis. No less than 242 persons of very diverse nationalities received the antirabic treatment; 5 were Persians, 4 Greeks, 32 Armenians, 5 Tartars, 10 Germans, 110 Russians, &c. Bites from dogs were principally recorded; but there were also 6 from horses, 2 from cats, and 1 from a donkey. The mortality, as estimated according to the Pasteur method, only amounted to 0·45 per cent. An extremely remarkable case is specially recorded, in which a station-master was treated for hysteria, he having no recollection of ever having been bitten by any animal whatever. On being, however, repeatedly pressed, he recalled having been bitten, a year and seven months previously, by a dog in the chest. The characteristic symptoms of rabies soon declared themselves; the patient was not, however, treated for hydrophobia, and he died. Subsequent inoculations proved that he had succumbed to undoubted rabies. So prolonged a period of incubation for hydrophobia is, we believe, unknown. Experiments were conducted at the station to determine the action of Röntgen rays on the virulence of rabid marrows, and it was found that the virulence was diminished slightly by considerable exposure to these rays. Researches were also carried out to ascertain how long rabid marrows can be preserved in glycerine and water without losing their virulence, and the period, Dr. Frantzius tells us, is a longer one than Roux, Nocard, and other investigators have thought.

THE so-called canning industry has made such vast strides all over the world, and notably in America, that it is not surprising that this method of preserving foods should form the subject of inquiry at the hands of the bacteriologist. When we learn that in Baltimore alone 1,250,000 bushels of oysters are annually canned, and that the United States is responsible for 120,000,000 cans of tomatoes, and of other articles, such as fish of various kinds, and fruits, &c., in similarly large numbers, it is remarkable that Messrs. Prescott's and Underwood's paper, "Micro-organisms and sterilising processes in the canning industry," published in the *Technology Quarterly*, should be the first contribution to so important a subject. These gentlemen have specially studied the bacterial flora of canned clams and lobsters which have broken down, or, in other words, been imperfectly preserved. In every case where "spoiling" had occurred, bacteria were present in large numbers, whilst in no instance were any discovered in sound cans. Sometimes only a single variety, or a pure culture of a particular microbe, was found in unsound cans, but usually the latter contained a mixture of several species. Nine different bacteria were selected and isolated for subsequent study, both as regards their macroscopic and microscopic appearances; two of these were cocci, the remainder bacilli forms. These bacteria were afterwards inoculated into the contents of sound cans, with the result that the latter invariably decomposed, whilst experiments were also made to test the method of applying heat to canned articles which would most effectually destroy the chances of these micro-organisms surviving and spoiling the contents. An account of the numerous experiments carried out by the authors on this highly important commercial side of the inquiry will be published later; meanwhile their investigations go to show that, given a proper control of the temperature, it is possible to preserve clams and lobsters with absolute certainty, and in a more perfect condition than has hitherto been possible.

The *Journal de Physique* for November contains a specially good collection of abstracts of physical papers, in addition to an important paper by M. Gerrit Bakker, on the thermodynamic properties of liquids with simple molecules, and a note by M. J. Schurr, on electric resistance and self-induction.

From Mr. F. W. Frankland, of New York, we have received several papers on the "Theory of Discrete Manifolds," dealing with the postulates of Euclidian geometry and their hypothetical counter-propositions, space-curvature, and the geometric axioms. Almost concurrently with these essays, Signor G. Veronese gives in the *Atti dei Lincei* a disquisition on the postulate of continuity, in which he arrives at certain conclusions contrary to the views of Schönflies.

Some ten years ago, Weber discovered that a heated body begins to emit visible radiations at a lower temperature than that at which it exhibits the well-known glow of red heat. This "grey-glow," as it has been termed, has been investigated from a physiological standpoint by Herr O. Lummer (*Annalen der Physik und Chemie*, 62). According to the author's theory the observed appearances are due to the different susceptibilities of the rods and cones of the retina to light of varying intensity, the grey-glow being perceptible only to the rods, while the red-glow stimulates the cones. It is proposed to make observations of the lowest temperature at which luminosity occurs. Herr Lummer expresses the view that this temperature depends in some degree on the area of retinal surface exposed to the radiations.

From a series of investigations on the temperature-coefficient of the potential of the calomel electrode (*Proceedings of the American Academy of Arts and Sciences*, xxxiii. No. 1), Mr. Theodore William Richards draws the following conclusions: (*a*) The temperature-coefficient increases with the dilution of the electrolyte; (*b*) the kation of the electrode influences the result by affecting the degree of dissociation of the chloride in solution; (*c*) both of these effects may be approximately computed by a simple logarithmic formula based upon Nernst's hypothesis; (*d*) the accuracy of the results is, however, affected by at least one important modifying influence, the "catalytic" decomposition of mercurous chloride into mercuric chloride and mercury; (*e*) this side reaction is responsible for the slight inconstancy of the normal calomel electrode; (*f*) the "decinormal electrode" is much more uniform in its behaviour than the normal, and hence for some purposes might be a more useful means of measuring potential differences; (*g*) hydrochloric acid and ammonic chloride are anomalous in their behaviour.

Among recent contributions to systematic botany are "North American Lemnaceæ," by Mr. R. C. H. Thompson, all four genera which comprise the order being represented; and "Contributions to the Flora of Queensland," by Mr. F. M. Bailey, in which two new species of *Nepenthes* are described and figured.

The *Botanical Gazette* states that another botanical journal has entered the field as a popular magazine in America. The *Asa Gray Bulletin* has ceased to be the organ of the Agassiz Association, and has entered upon a larger field. It will in future be published monthly, at Washington, D.C.

The last issue (Appendix I., 1898) of the *Kew Bulletin of Miscellaneous Information* consists of a list of seeds of hardy herbaceous plants, and of trees and shrubs (mostly ripened at Kew during 1897), available for exchange with colonial, Indian, and foreign botanic gardens, as well as with regular correspondents of Kew.

Two useful publications recently received from the U.S. Department of Agriculture (Division of Vegetable Physiology and Pathology) are "The Bermuda Lily Disease," by Mr. A. F. Woods, attributed by the author to a variety of causes, chiefly negligent horticulture; and "Notes on the Grasses and Forage Plants of Iowa, Nebraska, and Colorado," by Prof. L. H. Pammel, illustrated by a number of excellent woodcuts. Dr. E. F. Smith sends us a reprint from the *Centralblatt für Bakteriologie, Parasitenkunde, und Infektionskrankheiten* (in English), on *Pseudomonas campestris*, the cause of a brown rot in cruciferous plants caused by a Schizomycete, hitherto known as *Bacillus campestris*. Having only a single long polar flagellum, the author regards it as belonging to Migula's genus *Pseudomonas*. The life-history and effects of the parasite are described in detail.

The second edition of a series of "Laboratory Tables for Qualitative Analysis," drawn up by the demonstrators in chemistry of the Owens College, Manchester, has been published by Mr. J. E. Cornish. The tables show in a systematic way, how the student should proceed to examine a solid substance, to make a preliminary examination for acids, to examine acid mixtures, or make a preliminary examination of an organic substance. Following these instructions are tables for the various groups of metals. Each schedule or table occupies one sheet (except the two first tables, which cover two sheets each). The tables are thus handy for use in chemical laboratories where simple analysis has to be carried on, though the demonstrators themselves would often prefer to give the laboratary work a more educational value if they were at liberty to do so, or if time enough was allowed them. Where a course of qualitative analysis is a part of the curriculum, and the demonstrator has thirty or forty students to look after, the tables should be found useful, for they will save the student from worrying his instructor with unnecessary questions.

The additions to the Zoological Society's Gardens during the past week include a Common Marmoset (*Hapale jacchus*) from South-east Brazil, presented by Mr. G. Willison; an African Brush-tailed Porcupine (*Atherura africana*) from West Africa, presented by Captain W. C. Woollett; a Flat-backed Terrapin (*Cyclemmys platynota*) from Johore, Malay Peninsula, presented by Mr. S. S. Flower; a Leopard Tortoise (*Testudo pardalis*) from South Africa, presented by Miss E. Harold; a Hawk's-billed Turtle (*Chelone imbricata*) from the East Indies, two Scorpion Mud Terrapins (*Cinosternon scorpioides*) from Guiana, eleven Dumeril's Grieved Tortoises (*Podocnemis dumeriliana*) from South America, presented by Dr. J. Bach; a Smooth

Snake (*Coronella austriaca*) from Hampshire, presented by Mr. E. Penton; a Mozambique Monkey (*Cercopithecus pygerythrus*, ♂) from East Africa, a Red Deer (*Cervus elaphus*), European, deposited; two Bridled Wallabys (*Onychogale frenata*) from Australia, an Electric Eel (*Gymnotus electricus*) from South America, purchased.

THE illustrations for Profs. Parker and Haswell's forthcoming "Text-book of Zoology" have been drawn by Mr. M. P. Parker, and not Mr. N. J. Parker, as announced last week.

OUR ASTRONOMICAL COLUMN.

THE VARIABLE STAR *o* CETI (MIRA).—For many years past the brightness of this star at maximum has not come up to expectation, neither has its time of maximum occurred when predicted, a fact which might be accounted for by an irregularity of some twenty-five days either one way or the other. This year, however, as observed on November 28 by Mr. Shackleton, it was already brighter than γ Ceti (3·38), and nearly as bright as *a* Ceti (2·44) (Oxford Uranometria), so that its magnitude will be about 2·9. Another observation on November 29, made at the Solar Physics Observatory, South Kensington, by the same observer and Mr. Butler, gave its brightness equal to γ Eridani (2·8) (U.A) (3·0 H.P.).

The predicted and observed maxima for the last three years are as follows:—

	Predicted (*Observatory* Companion).	Observed.	Mag.
1895	December 9	February 27	3·8
1896	November 3	February 1	3·5
1897	November 9	?	(2·9)?

From the observations of last year and the period of 332 days, it should be at its maximum about December 30, so that it may still be expected to increase in brightness, though its light curve is very irregular near maximum.

THE COMING TOTAL SOLAR ECLIPSE.—Owing to the presence of the plague in some parts of the country near the line of central totality, several parties intending to observe the total solar eclipse of January 22 next have had to make new arrangements. At present the following seems to represent the locations of the several parties on the central line. The most western station, Viziadurg, will be occupied by Sir Norman Lockyer with his party, backed up by the officers and crew of one of Her Majesty's ships. Karad, the next station to the east, lying on the Southern Mahratta railway, will be the place of observation by Prof. Michie Smith with his party from the Madras Observatory. Prof. Naegamvala with his followers will also probably adopt this region for work. Further to the east lies Talni, where Mr. Newall, Captain Hills, and a party from the British Astronomical Association will be stationed. Where the central line of totality cuts the road between Nagpur and Seoni, Dr. Copeland will take up his station, while about 150 miles further along the track, at Sohagpur, the Astronomer Royal and Prof. Turner will be stationed. Still further eastward, at Buxar on the Ganges, will be located two parties—one consisting of a second section of the British Astronomical Association, and the other the main party of the Great Indian Trigonometrical Survey. It is also likely that the Japanese astronomers will be in this neighbourhood. At another station, still further along the line, it is stated that the Fathers of the St. Xavier's College, Calcutta, will make observations. Profs. Campbell, Schaeberle, Todd, and not improbably M. Deslandres, will be present somewhere on the central line, but the actual positions they will take up are not yet definitely known.

SYSTEMATIC OBSERVATIONS OF OCCULTATIONS.—Herr H. Batterman has recently published (*Astr. Nach.*, 3457-8) the individual observations of a very complete set of occultations of stars by the moon, numbering altogether 641. The instrument he employed was a Merz refractor of 6 inches aperture and 8 feet focal length, and was set up at the Berlin Observatory. The object of these observations was to determine the parallactic inequality of the moon, and thence the parallax of the sun. For such an undertaking it was necessary to make observations on as many days as possible, especially near the time of full moon; the observations had, further, to be regular as regards immersion and emersion, and homogeneous as much as possible over the lunar orbit. Herr Batterman was handicapped very considerably by the local conditions of Berlin, and by being restricted as regards his visible horizon; but, nevertheless, he was able to secure a considerable number of observations in the two and a quarter years he devoted to them. This communication contains simply the individual observations, but he hopes at some future date to publish the results when the large work of computation has been completed.

THE VARIABLES S CEPHEI AND T URSÆ MAJORIS.—Mr. C. E. Peek, who is the owner of the Rousdon Observatory, Devon, has just published two very interesting series of observations relating to the light changes of the variables S Cephei and T Ursæ Majoris. All the observations were made with a Merz 6·4-inch equatorial refractor, and each is the mean of fine visual comparisons with stars that are seen in the same field of view as the variable. The author does not, however, state his actual method of observing, but we presume that this will be included in the introduction (No. 1) which he proposes to issue subsequently. In addition to the list of the individual observations, Mr. Peek has plotted the curves representing the light changes during this period of ten years (1887-1896 inclusive) over which the observations extend. These curves do not appear to have been smoothed, so that they represent the observed light fluctuations. In the case of T Ursæ Majoris, there is a very suggestive brightening about the time of minimum in nearly all the curves of this variable here drawn, and it would be interesting to know if other observers have recorded it.

SOME SYSTEMS OF METEORS.—Prof. Th. Bredikine contributes to the *Bulletin* of the St. Petersburg Academy (5th series, vol. v. No. 5) an investigation with the object of determining which member or members of our solar system have a disturbing action on those systems of meteors which the earth passes through in her revolution round the sun. The disturbing agents taken into account are: the action of some major planet, that of the earth, which is somewhat of the second order, and last, but not least, that of the sun, whose power acts in two ways, namely, first by attraction, and secondly by creating great disturbances in the nucleus. In nearly all cases the sun's effect is predominant, especially when the distance at perihelion passage is small, but sometimes a near approach to one of the major planets is very marked. Prof. Bredikine has previously shown that from an examination of comets' tails the force of projection at the times of outbursts is sufficient to convert the orbits of several of the composing particles from parabolic to elliptic of short period. He assumes that all meteor streams contain particles originally belonging to comets which passed through the solar system, and lost matter by disturbing actions of the members of this system. Employing as a starting-point the positions of some of the more prominent radiant points, as given in the catalogue published by Mr. Denning in the *Monthly Notices* (May 1890), he investigates the probable disturbing agent in each case. Most of the meteor streams dealt with have, according to this investigation, resulted from large disturbances at the nucleus caused by the sun itself; among these are the Leonids, Quadrantides, Geminides, Aquarides, &c. The Orionides owe their presence to the planet disturbing influence of Jupiter, while the Lyrids are due to that of Saturn.

COMET PERRINE (OCTOBER 16).—The ephemeris of comet Perrine, which we have recently given in this column, begins now to indicate variations from the observed place. Herr Möller (*Astr. Nachr.*, No. 3459) has therefore determined new elements from the variation of proportionate distances, using the observations made on October 16, Mount Hamilton; October 24, Hamburg; and November 1, Arcetri, Florence. The following are the new computed positions:—

Ephemeris, 12h. Berlin M.T.

THE ANNIVERSARY MEETING OF THE ROYAL SOCIETY.

TUESDAY last being St. Andrew's Day, the anniversary meeting of the Royal Society was held in their apartments at Burlington House. The auditors of the Treasurer's accounts having read their report, and the Secretary having read the list of Fellows elected and deceased since the last anniversary, the President (Lord Lister) proceeded to deliver the anniversary address. The medals were then presented.

The Society next proceeded to elect the officers and council for the ensuing year. The following is a list of those elected:— President: Lord Lister. Treasurer: Sir John Evans, K.C.B. Secretaries: Prof. Michael Foster, Prof. Arthur William Rücker. Foreign Secretary: Sir Edward Frankland, K.C.B. Other Members of the Council: Prof. William Grylls Adams, Prof. Thomas Clifford Allbutt Sir Robert Stawell Ball, Rev. Thomas George Bonney, Prof. John Cleland, Prof. Robert Bellamy Clifton, Prof. James Alfred Ewing, Mr. Alfred Bray Kempe, Dr. John Newport Langley, Dr. Joseph Larmor, Prof. Nevil Story Maskelyne, Prof. Raphael Meldola Prof. Edward Bagnall Poulton, Dr. William James Russell, Dr. Dukinfield Henry Scott, Prof. Walter Frank Raphael Weldon.

The following is the address of the President:—

Since the last anniversary meeting fifteen Fellows and six Foreign Members have passed away.

The deceased Fellows are—

Edward Ballard, January 19, 1897, aged 76.
Charles Tomlinson, February 15, 1897, aged 89.
Samuel James Augustus Salter, March 1897, aged 72.
James Joseph Sylvester, March 15, 1897, aged 83.
Edward James Stone, May 9, 1897, aged 66.
Major-General Robert Mann Parsons, May 20, 1897, aged 68.
Sir Augustus Wollaston Franks, May 21, 1897, aged 72.
Sir John Charles Bucknill, July 19, 1897, aged 79.
Right Hon. Anthony John Mundella, July 21, 1897, aged 72.
William Archer, August 14, 1897, aged 65.
Lieutenant-General Sir William Francis Drummond Jervois, August 17, 1897, aged 76.
John Braxton Hicks, August 28, 1897, aged 74.
Charles Smart Roy, October 4, 1897, aged 43.
James Heywood, October 17, 1897, aged 87.
Rev. Samuel Haughton, October 31, 1897, aged 76.

The Foreign Members are—

Emil Heinrich du Bois Reymond, December 26, 1896, aged 79.
Carl Weierstrass, February 20, 1897, aged 82.
Alfred Louis Olivier Des Cloiseaux, May 8, 1897, aged 79.
Julius von Sachs, May 29, 1897, aged 65.
Johannes Japetus Smith Steenstrup, June 20, 1897, aged 84.
Rudolph P. H. Heidenhain, October 1897, aged 63.

Of these some seem to demand special notice from this Chair.

In Sylvester, English mathematical science has lost one of its best known and most gifted exponents. During his long and active career he wrote several hundreds of memoirs on the most refined and technical parts of pure mathematics. It is not for me to attempt to enumerate even the most important of his labours, which were as solid as they were brilliant. To quote the words of one well qualified to judge, "originality, imagination, and enthusiasm were the ever present notes in the chords which he struck with a master's hand; and it may be safely predicted that he will always find an honoured place in the small roll which contains the names of the men who have been pre-eminent in the science which he loved and to which he devoted his life."

Our Fellow for more than fifty years, he received the highest recognition our Society can bestow, having been awarded a Royal Medal in 1861, and the Copley Medal in 1880. No less was he honoured by other countries, foreign scientific academies having showered their distinctions upon him. Thus full of honours, as of years, he died at the advanced age of eighty-three.

In Sir Augustus Wollaston Franks we have lost one of the most distinguished archæologists of this or any other country. During a connection with the British Museum extending over a period of forty-five years, he practically founded the Department of British and Mediæval Antiquities and Ethnography, and its growth was in no small degree due to his private liberality. In all that related to the subject of the antiquity of man, he was one of our first authorities; and the Christy collection of which he was a trustee, and which is now incorporated with the British Museum, assumed its present great importance under his careful superintendence and through his generous aid. The mediæval collections which he bequeathed to the nation testify alike to his taste and judgment and to his rare munificence.

The Rev. Dr. Haughton was a man of great intellectual power and amazing versatility. He made original contributions, based often upon very laborious researches, to physics, chemistry, geology, biology, and medicine, while continuing to discharge from time to time the functions of a minister of the gospel. If his many-sidedness prevented him from attaining a high eminence in any one branch of science, it pre-eminently fitted him for the place he was to fill in the government of a large educational institution.

After receiving his school education in his native town of Carlow, he proceeded to Trinity College, Dublin, where, his brilliant studentship having procured him a Fellowship at an unusually early age, he threw himself with great zeal into the educational work of the University. As a boy he had been fond of geology, and as a young man he so greatly distinguished himself in it that at the age of thirty he was appointed to the Geological chair in Trinity College. Here he found himself unable to deal satisfactorily with fossil remains without a knowledge of comparative anatomy, and for this an acquaintance with human anatomy seemed an essential preliminary. Thus he was drawn to Medicine, for which indeed he had an early predilection; and entering comparatively late in life on medical study, he devoted himself to the entire curriculum with characteristic energy. Soon after he had taken his medical degree, an epidemic of cholera occurred in Dublin, and he showed the true spirit of a devotee of Medicine by placing himself at the head of a band of medical students, to supply the want of any adequate system of nursing. In this self-denying labour Haughton bore more than his full share, and its beneficial results left in his mind an abiding sense of the value of bedside work. He was thus led to found medals for the encouragement of clinical study; and the last act of his life was, out of very scanty savings, to provide for making those rewards more substantial.

In the course of his studentship he had been deeply impressed with the abuses which then existed in the medical department of Trinity College, and on becoming connected with the governing body, he entered on the task of reform with indomitable courage; and it was mainly due to his exertions that the school was raised from a comparatively subordinate position to the leading place which it now holds.

The high opinion entertained of him by his colleagues was shown by the fact that he was for many years their representative on the General Medical Council. He was of a most genial and loyal nature, and it is said of him that, while he made many friends, he never lost one.

Edward Ballard was one of the chief promoters of the sanitary science of the Victorian era. His researches into problems regarding public health, which extended over forty years, were characterised by very remarkable far-sightedness and exactitude. To him we are indebted for most of our certain knowledge on the subject of effluvium nuisances in their relation to health, and for the indication of trustworthy means of mitigating the deleterious influences of noxious trades. He, too, was among the first to insist on the importance of strict study of the ætiological relations of "sickness" and "mortality"; and by his labours in this connection he laid a foundation for that system of compulsory notification of infectious illness which is now practically universal in this country. But Dr. Ballard's completed work in these and other directions by no means represents the full measure of the value of his services to public health. By his industry in the accumulation of facts bearing on a number of unsolved problems, and his exposition of such facts in their several connections, he has not only indicated lines of further research, but has tended to lighten the labours of those who will come after him. He was a man of noble nature; and the devotion of his great abilities to the service of mankind was utterly devoid of self-seeking.

James Heywood was a man of considerable scientific attainments, who deserves to be specially remembered on account of his great services in the cause of university reform. He was born in 1810 at Everton, Lancashire, and on leaving school at Bristol, entered Trinity College, Cambridge, where he was

Senior Optime in 1833. He could not, however, proceed to his degree until twenty-three years later, on account of the religious tests which were only abolished in 1856 by the Cambridge University Reform Act. Of this, as member for North Lancashire, he was the chief promoter: for, already in 1854, he moved and carried, after several previous attempts, a clause by 233 against 78, in favour of the abolition of religious tests for the Bachelor's degree in Arts, Laws, Medicine, and Music. There can be no doubt that this fundamental reform led the way to the introduction of experimental science into our universities.

He was one of the original trustees of Owens College, Manchester, and took a keen interest in the establishment and development of the scientific chairs in that institution. He was elected into the Royal Society in 1839, and was, at the time of his death, the Fellow of longest standing.

On February 19 last, Karl Weierstrass, one of our Foreign Members, died in his eighty-second year. He was elected a Foreign Member in 1881, and in 1895 the Copley Medal was awarded to him in recognition of the contributions he had made to pure mathematics. The grounds on which the award was made were set out in the President's Address in that year; and so it is not necessary now to refer in detail to his researches. The results which he obtained and the rigorous precision of method which he adopted have made his influence remarkable; and it can fairly be claimed for him that he is not the least eminent on the roll of the great mathematicians of the century.

Alfred Des Cloizeaux was a veteran mineralogist of great eminence. His first paper was published fifty-four years ago, and was the beginning of a long series treating of the forms and optical characters of crystals. After being Professor of Mineralogy for eighteen years at the École Normale Supérieure, he was appointed to the charge of the minerals at the Musée d'Histoire Naturelle, in which office he remained until he reached the limit of age prescribed by the rules of the French Civil Service. His fame rests upon the thoroughness and accuracy of his systematic investigation of the crystals of minerals, more especially as regards their optical properties. The results are incorporated in his "Manuel de Minéralogie," a standard book of reference. Prof. Des Cloizeaux died in the eightieth year of his age.

In Julius von Sachs botanical science has lost one of the most conspicuous figures of the latter half of the century. His widespread influence was due in the main to two memorable books. In his "Experimental-Physiologie" (1866) he at once put the subject on a new footing. He returned to the methods long ago pursued by Hales and Knight in this country, and, while giving a critical estimate of the results achieved by his predecessors, everywhere turned the light of experimental investigation on the problems presented by the living plant. The success which he met with was due to a broad grasp of general principles and a singular directness of aim at the object in view, associated with great experimental skill. In his mechanical ingenuity and aptitude for making simple yet effective appliances he somewhat resembled Faraday.

His "Lehrbuch" (1868) produced a profound impression on the teaching of botany both in Europe and America. It did for botany what Gegenbaur achieved for zoology, in presenting the morphological facts of the vegetable kingdom for the first time as a whole. As with the "Experimental-Physiologie," it was no mere compilation, but was at every point subjected to the test of original investigation.

Sachs, moreover, presented the somewhat unusual combination in science of great gifts of original investigation accompanied by no less great gifts of exposition. The insight of his attack on a problem was equalled by the masterly lucidity with which he expounded his results.

Emile du Bois-Reymond, who died in December of last year at the age of seventy-eight, was a Foreign Member of the Royal Society since 1877. Although born in Berlin, he was of French-Swiss extraction, his father being a native of Neufchâtel, and his mother belonging to a French Huguenot family. He studied in the Universities of Berlin and Bonn, and took his Doctor's degree in Medicine in Berlin. In 1840, at the age of twenty-two he became the assistant of Johannes Müller, whose successor he was appointed, in the chair of Physiology in Berlin, in 1858. He has himself told us that it was Johannes Müller who first turned his attention to the study of animal electricity, to which the labours of his life were chiefly devoted. His publications on the subject were very numerous, while his observations were characterised by mathematical accuracy which stamped them as trustworthy. And it is not too much to say that his discoveries constitute the main fabric of our knowledge of animal electricity.

Although his energies were chiefly devoted to one branch of physiology, he was not unmindful of other departments of the science. Ever since 1859 his name has been associated with the editorship of the "Archiv für Anatomie und Physiologie," which he carried on in conjunction with Reichert, after the death of Johannes Müller. He was a man of wide sympathies and high culture. His semi-popular discourses, scientific, literary, and historical, are models of well-selected language, clear exposition, and deep erudition. His address "On the Limits of Natural Knowledge" has passed through numerous editions, and has been translated into many languages. Du Bois-Reymond ranks with men like Bernard, Brücke, Helmholtz, and Ludwig, as one of those by whom the science of modern physiology has been built up.

As regards the work of the Society during the past year I have little to add to the Council's Report.

On July 15 I had the honour of taking part in a deputation to the Queen at Windsor to present the address of congratulation which had received the sanction of the Society. On this memorable occasion I was accompanied by the other officers, including all the Vice-Presidents, and also by three former Presidents, whom we all revere, Sir Joseph Hooker, Sir George Stokes, and Lord Kelvin. Her Majesty received us in person, and made the following very gracious reply:—

"I thank you for your loyal and dutiful Address. I am much gratified by the attachment which your ancient and learned Society expresses to my Throne and Person.

"I am fully sensible how far the labours and ingenuity of men of science, whom you worthily represent, have advanced the industrial and social prosperity of my people, and have tended alike to their good and refinement, and I confidently expect the same excellent fruit in years to come from the indefatigable and reverent investigation of nature for the promotion of which the Royal Society was founded."

In the early part of the year a deputation from the Royal Society, the British Association, and several others of the most important scientific and technical societies, waited upon the Prime Minister to urge upon him the importance of establishing in this country a National Physical Laboratory in which the testing and verification of instruments and the construction and improvement of standards of various kinds should be undertaken in a regular and systematic way. There was nothing new in principle in this proposal. Work of the kind referred to has for many years been carried out at Kew under the auspices of the Royal Society. It has been as successful as the limited means at the disposal of the Kew Observatory Committee would allow; and all that is needed is sufficient State aid to enable work of the same kind to be done on a larger and more useful scale.

It is satisfactory to be able to state that the efforts of the deputation were not in vain. A committee, of which Lord Rayleigh is chairman, has been appointed by the Treasury to investigate and report upon the desirability of the scheme. Evidence is being taken, and we may fairly hope that the Government will finally consent to promote an undertaking which could not fail to advance the interests both of pure science and of scientific industry.

In January last I was requested by the Council to approach the India Office in order to call their attention to Yersin's treatment of bubonic plague, which was causing such grave anxiety in the Bombay Presidency. I gladly undertook this service, as I had been greatly impressed with an account which that distinguished man, himself an independent discoverer of the plague bacillus, had given of a trial he had made of his remedy in China. The cases were, indeed, not very numerous, but the success recorded was most striking, and was in every detail so exactly proportioned to the shortness of the duration of the disease at the time when the treatment was begun that it was difficult to conceive it to be a matter of accidental concomitance. A similar correspondence of results with theory, taken along with complete trustworthiness of the source of information, had made me early feel and express confidence in the analogous serum treatment of diphtheria, which has since proved of such signal benefit to the community.

I was received at the India Office with the utmost cordiality, and I am not violating confidence when I say that my representations tended to strengthen the Home Government in their disposition to afford encouragement to M. Yersin to labour in the stricken district.

The vague rumours which reached us some time ago regarding his work in Bombay were not of an encouraging character. But I was glad to see from a paper read lately by M. Metchnikoff at the International Medical Congress in Moscow, that the treatment had been by no means a complete failure, and that the smaller degree of success than that obtained in China was sufficiently explained by the fact that the serum in the present state of knowledge takes a very long time to prepare, and Yersin had been obliged to employ what he knew was not as potent as that which he used in China. We may therefore fairly hope that in due time, if the pestilence should last so long, the original full measure of success will be again obtained.

The communications made to the Society during the year have been of a high order of excellence. In illustration of this I must content myself with referring to two examples taken from the domains of physics and biology respectively. The remarkable series of ten papers by Profs. Dewar and Fleming, describing their continued researches on the electric and magnetic properties of matter at low temperatures, have brought before us new facts of fundamental importance. Such, for instance, is their discovery that at very low temperatures the electrical resistance of bismuth is remarkably increased by transverse magnetisation; so much so that the observations seem to indicate that at the absolute zero pure bismuth would be a perfect conductor if not in a magnetic field, but a perfect non-conductor if transversely magnetised.

The illustration which I will take from the domain of biology is the recent communication of Mr. Gardiner on the Histology of the Cell-Wall. Before 1883, when his former paper on this subject was published in our *Proceedings*, other observers had seen and described threads passing through the walls of certain vegetable cells, and supposed to connect the protoplasm of one cell with that of adjacent ones. But the observation had only been made in certain exceptional cases, and, moreover, they were not of such a character as in Mr. Gardiner's specimens to afford conclusive evidence that the threads really consisted of protoplasm. Since the date referred to he has laboured at this most important subject with remarkable ingenuity and perseverance; and by new methods of preparation varied to overcome the special difficulties presented by the various forms of tissue, he has succeeded in demonstrating, throughout the long series of cases which he has already examined, the presence of threads of undoubtedly protoplasmic nature, often of exquisite delicacy, passing in large numbers through the walls of adjacent cells, not only where they are thinned by the presence of pits, but elsewhere also. And to use his own words, "there can be little doubt that such connecting threads occur universally in the cells of all the tissues of all plants. From this arises the fundamental conception that the plant body must be regarded as a connected whole." And the transmission of impulses and of nutrient material from one part of the vegetable organism to another, quite unintelligible as long as the protoplasm of each cell was believed to be shut off from that of its neighbours by a wall of cellulose, receives a ready explanation.

The attendance at our meetings during the past session has been very satisfactory. There can be no doubt that the great improvement which has taken place of late years in this respect has been in no small measure due to the alteration of the time of meeting to the afternoon, which is more convenient to the large majority of the Fellows than the evening. I thus freely admit that the change has been very advantageous, although I was opposed to it when it was made, as I was apprehensive that it would interfere with participation of members of my own profession in the work of the Society; for I should greatly regret anything like a severance of Medicine from the Royal Society, believing as I do that they are very helpful to each other, medical practice affording the suggestion and stimulus of much scientific investigation, while it is often the ultimate test of the validity of the conclusions arrived at.

At the risk of seeming to dwell too much upon matters connected with the healing art, I am tempted to refer to one recent instance of its intimate connection with science. In the Society's *Proceedings* for 1893 (vol. liv. p. 187) appeared a paper by Dr. Monkton Copeman, relating important researches on Variola and Vaccinia, and referring to a discovery which he had announced two years previously at the International Hygienic Congress, in London (*Trans.* of Internat. Congress of Hygiene, 1891), that an admixture of glycerine in certain proportions with vaccine lymph derived from the calf had the effect of causing, in no long time, the disappearance of what he termed the "adventitious microbes" invariably present in that material at the outset, without diminishing the efficacy of the lymph for the purpose of vaccination. It had been known before that glycerine might be added to the lymph without destroying its vaccinal property, but that it would thus cause the disappearance of concomitant microbes was quite new. In the scant intervals of leisure permitted by his duties as inspector under the Local Government Board, Dr. Copeman has continued to prosecute his researches. He has ascertained, among other things, that if tubercle bacilli are intentionally mixed in considerable quantity with the lymph, they soon lose their life under the influence of the glycerine, thus removing the last rational objection that could be urged against vaccination. For while the use of calf lymph excludes the possibility of conveying human disease in general by the process, the cow, like man, is liable to tuberculosis. It is true that tubercle is very rare in the young animal, and that the practice of killing the calf after it has furnished the vaccine and subjecting the body to competent inspection before the lymph is set aside for use, would reduce the risk of communication of the disease almost to zero. But it is satisfactory to learn that Dr. Copeman's process makes such a thing absolutely impossible. It further turns out that the use of the glycerine, so far from impairing the efficacy of the lymph for vaccination, considerably enhances it; so that it becomes susceptible of large dilution, one calf thus furnishing material for a much greater number of vaccinations than was formerly thought possible. And further the glycerinised lymph being stored in sterile glass tubes, the chance of contaminating the vaccination scratches with extraneous impurities, somewhat difficult to prevent in vaccinating directly from the calf, is entirely avoided. Lastly, it has been found that the inflammatory disturbance at the seat of vaccination in the human arm, with concomitant febrile disturbance, is greatly lessened by the use of the pure essential ingredient.

Comparatively little advantage has yet been taken of the system in this country. But it has been otherwise abroad; and the English Commission on Vaccination having made favourable reference to the subject, the President of the Local Government Board recently requested their Medical Officer, Sir Richard T. Thorne, to make a tour of inspection of the continental practice. In this he was accompanied by Dr. Copeman, and we learn from the report which they have issued that they found our countryman's precepts very extensively acted on in the various countries which they visited. In Germany, especially, they are carried out with the thoroughness characteristic of that nation, so much so that while arm to arm vaccination has been entirely discarded, the use of glycerine-stored lymph has almost entirely superseded the practice of vaccinating from calf to arm.

It has given me pleasure to learn that Mr. Chaplin is likely soon to propose legislation for the purpose of giving the full benefits of this valuable process to the country of its discoverer.

It afforded great though melancholy satisfaction to the Treasurer and myself to be present last Christmas at the final obsequies of the man to whose labours is due the possibility of carrying on such investigations as those just referred to. M. Pasteur was buried in his own "Institut" with a splendour befitting the memory of so great and good a man.

I have also been glad to be the means, as President of the Society, of aiding our French brethren in erecting a monument to him to whom the world in general owes so much. Having received last year a letter from the Perpetual Secretary of the French Academy inviting my help in raising a fund to supplement that which was being subscribed in France, I called a meeting held here on March 26 of last year, at which it was decided to form a committee, in order to collect contributions to the International Pasteur Memorial. I wrote in the first instance to such of our Fellows as are members of the Academy, requesting them to allow their names to be on the committee, and received in almost every instance a cordial assent. Our Treasurer having consented to act as treasurer to the fund, and Prof. Percy Frankland undertaking the somewhat onerous duties of secretary, a sum has been raised, amounting in all to 877*l.* 0*s.* 3*d.*, from which 17*l.* 7*s.* 2*d.* was deducted for expenses, leaving a balance of 859*l.* 13*s.* 1*d.*

I know that our French friends were much gratified by this result; and I learn from a letter written to the Treasurer by

M. Bertrand, acknowledging a final cheque, that the monument in Paris promises to be worthy of its object.

It is noteworthy that rather more than half the entire sum contributed has come from India, chiefly from the medical officers, through Surgeon-General Cleghorn. It seems probable that their great liberality was prompted by a sense of gratitude for the good work done on Pasteur's lines in that great dependency, such as Haffkine's preventive inoculations against cholera, and the efforts being made to cope with the plague in Bombay.

I have the sad pleasure, if I may so express myself, of announcing that my old friend, that distinguished medical officer and very gallant soldier, Sir William Mackinnon, late Director-General of the Medical Department of the Army, has, by will and codicils dated 1896 and 1897, after making certain specific legacies, including one of 2000*l.* to the University of Glasgow, bequeathed the whole residue of his property to the Royal Society, subject to certain life annuities. The proceeds of the fund are to be applied by the Royal Society for the foundation of such prizes and scholarships for the special purpose of furthering Natural and Physical Science, including Geology and Astronomy, and for furthering original research and investigation in Pathology, as the Society may think best and most conducive to the promotion of those sciences and of original discoveries therein; such prizes and scholarships to be called after the name of the testator.

COPLEY MEDAL.

Prof. Albrecht von Kölliker, For. Mem. R.S.

The Copley Medal is given to one who well deserves the highest honour that it is in the power of the Royal Society to confer. For nearly sixty years past Albrecht von Kölliker has made contributions of the highest value to histology, embryology, and comparative anatomy. Though his labours have embraced so wide a field, they have always been of a high order of excellence, and have often been of far-reaching significance.

His early histological discoveries were invaluable for the systematic development of the cell theory. Of these I must, on the present occasion, content myself with referring to two: his demonstration of the continuity between the nerve fibres and nerve cells of Vertebrata in 1845, followed by his memoir on nerve cells in 1849; and his isolation in 1848 of the cellular elements of smooth muscular tissue, together with his essay on the distribution of smooth muscle in the vertebrate body, and his final demonstration of the existence of muscular tissue in the walls of the blood-vessels, where its presence, although previously asserted by Henle and Sharpey, was at the time denied by Arnold and many others.

These are examples of the histological results achieved by von Kölliker during the first ten years of his scientific activity. They are of fundamental importance, and they have been followed by a long series of other valuable histological discoveries. The whole series show not only his power as an investigator, but the wide range of his knowledge, and the eagerness with which he has appreciated and applied whatever was new in the work of others. This last quality is well shown in his various essays on the structure of the nervous system, from his early acceptance of Remak's statements concerning non-medullated nerves, to his work of the last few years.

Prof. von Kölliker's influence upon histological science is due not only to his fame as an investigator, but in part also to his skill as a teacher and as a writer. Every successive edition of his text-book has been an important addition to the literature of the subject.

Among his embryological papers, that dealing with the development of Cephalopods, dating from 1844, is still a standard work, and figures copied from it are to be found in most modern text-books. His memoir on the development of Amphibia (1846) contains important statements on the behaviour of the nucleus during segmentation, and on the formation of cartilage and blood-vessels. The papers on the development of the skull (1849-50), and the subsequent work on the part played by the notochord and its sheath in the formation of the vertebral column, must be mentioned as of fundamental importance. His many later researches on mammalian embryology, which are summarised in the various editions of his text-book of vertebrate embryology, need not now be mentioned in detail.

Although it is as a histologist that von Kölliker is pre-eminently distinguished, his zoological papers are numerous and important. Among his labours in this direction were his early demonstration of the unicellular nature of the Gregarinidæ, his description of the Dicyemidæ, his memoirs on the structure and development of the Hydroids and Medusæ, and his later magnificent works on the Alcyonaria.

Many of von Kölliker's papers have appeared in the *Zeitschrift für Wissenschaftliche Zoologie*, founded by him and von Siebold in 1848, of which he is still one of the chief editors. It is pleasing to know that, at the advanced age of eighty, he is still able to prosecute with unflagging zeal his work as an investigator and as a teacher. One of the reasons of his absence to-day is his reluctance to leave his lectures.

ROYAL MEDAL.

Prof. Andrew Russell Forsyth, F.R.S.

One of the Royal Medals is awarded to Prof. Andrew Russell Forsyth on account of his contributions to the progress of pure mathematics.

He is known principally for his excellent treatises on many subjects of mathematical analysis. These works are not mere compilations; they contain original work, and exhibit great creativeness of thought.

The treatise on differential equations was immediately successful, and established firmly his reputation as a teacher. This was followed by a scholarly work on Pfaff's problem and, later, by the treatise on the Theory of Functions, the first in English on the subject, and noteworthy for the manner in which the parallel theories of Cauchy, Riemann, and Weierstrass are marshalled. The appearance of this work is responsible for the newly awakened interest in this country concerning the great works on this subject of Weierstrass, Jordan, Klein, Lie, Poincaré, and Mittag-Leffler.

Prof. Forsyth is, in addition, a prolific author on other subjects covering a wide range of pure mathematics.

ROYAL MEDAL.

Lieut.-General Sir Richard Strachey, F.R.S.

The other Royal Medal is conferred on Lieut.-General Sir Richard Strachey for his investigations in physical and botanical geography, geology and meteorology. Two of the most recent of these are recorded in his report, published in 1888, on the barometrical disturbances and sounds produced by the eruption of Krakatoa, and in his paper in the *Phil. Trans.* of 1893 entitled "Harmonic Analysis of Hourly Observations of the Temperature and Pressure at British Observatories." These, while important in themselves, were but the last of a long series of valuable memoirs. He was the first to treat scientifically of the physical and botanical geography, geology, and meteorology of the Western Himalaya and Tibet. His numerous papers on these subjects, dating from the year 1847, are published in the *Journals* of the Bengal Asiatic, Geological, and Royal Geographical Societies, in the Royal Society's *Proceedings*, and in the Reports of the British Association.

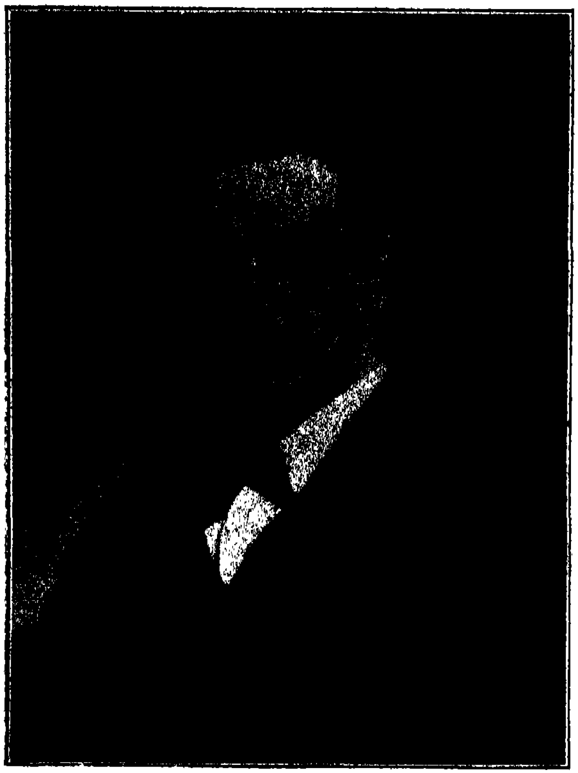
Sir R. Strachey's scientifically annotated and very complete botanical collections made in Kumaon, during his physical survey of that province (in company with Mr. Winterbottom), and in Tibet, at all elevations from 2000 to 18,500 feet, are unique in value and interest, as being the first from which could be determined the successive zones of vegetation according to altitude in the mountains of any part of Asia.

Sir R. Strachey is justly regarded as the founder of scientific meteorology in India, whether by virtue of his early personal labours in that branch of science, or for the zeal and energy with which, during his long career as a member, first of the Government of India in that country, subsequently of the Council of the Secretary of State, he promoted the establishment of meteorological observatories and stations all over our Eastern dominions. Nor were his exertions in this respect confined to meteorology, for there are few scientific institutions or publications now supported by the Indian Government which are not largely indebted for their existence or organisation to his efforts.

DAVY MEDAL.

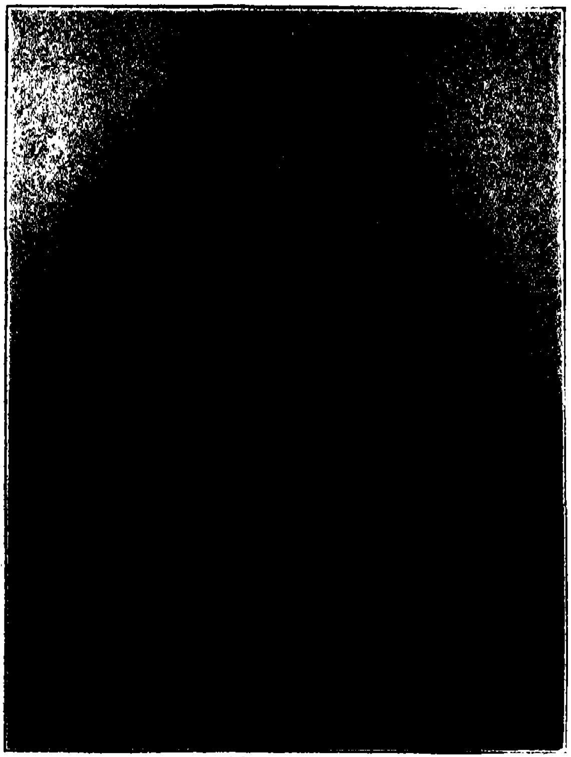
Dr. John Hall Gladstone, F.R.S.

The Davy Medal is awarded to Dr. John Hall Gladstone on the ground of the great extent and value of his chemical and physical researches, extending over a period of forty-nine years. His first paper was printed in 1847, and his last in the *Proceedings* of the Royal Society for 1896. During



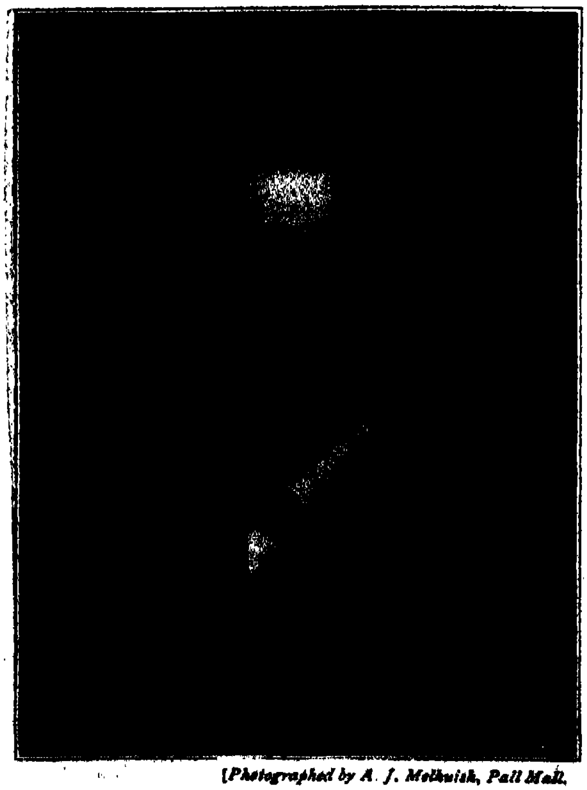
[*Photographed by Elliott and Fry, Baker Street.*

PROF. A. R. FORSYTH (ROYAL MEDALLIST).



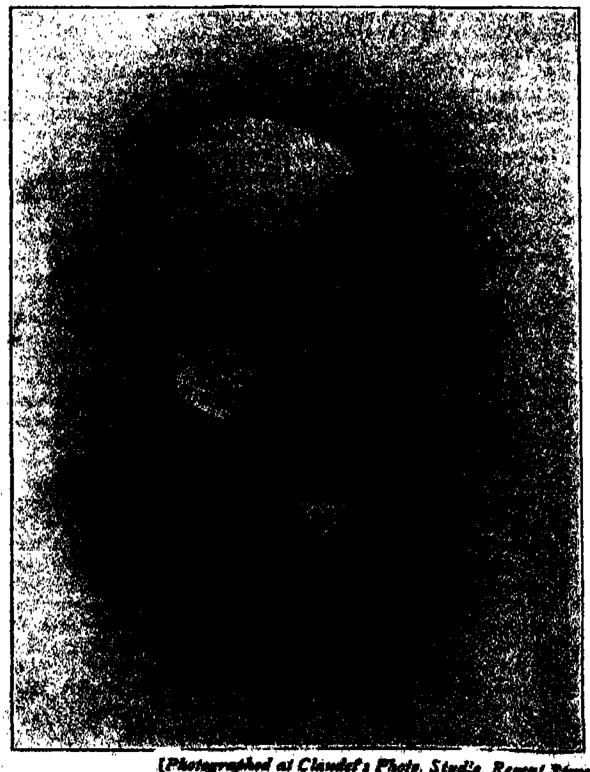
[*Photographed by A. J. Melhuish, Pall Mall.*

LIEUT.-GENERAL SIR RICHARD STRACHEY, G.C.S.I. (ROYAL MEDALLIST).



[*Photographed by A. J. Melhuish, Pall Mall.*

DR. J. H. GLADSTONE (DAVY MEDALLIST).



[*Photographed at Claudet's Photo. Studio, Regent Street.*

SIR JOHN SIMON, K.C.B. (BUCHANAN MEDALLIST).

this time he has published seventy-six papers, recording the results of his own researches, and forty-eight relating to investigations made in conjunction with other workers.

These papers cover a wide range of subjects. In chemistry he showed, in 1847, that urea is formed by the breaking up of some of the salts of fulminic acid. He demonstrated the composition of the so-called iodide of nitrogen. His memoir on the relations of the atomic weights of the elements suggested analogies with the homologous series of organic compounds. An important monograph on chemical affinity occupies forty-five pages of the *Philosophical Transactions* of 1855; in it the behaviour of salts in solution is discussed with much acuteness.

Amongst Dr. Gladstone's other very numerous contributions to chemical science, may be mentioned the study of the influence of carbonic anhydride on the germination of plants, his researches on the chemistry of storage batteries, on the molecular weight of caoutchouc and gums, and on the zinc-copper couple and its application to the production of organo-zinc compounds and the hydrides of the organic radicals Dr. Gladstone's new and simple method of producing organo-zinc compounds conferred a most valuable boon upon organic chemistry, and led to the very extensive use of these bodies in organic research, and consequently to many important discoveries in that domain of chemistry.

Amongst Dr. Gladstone's numerous researches in physical chemistry, may be mentioned the following:—"On the Spectra produced by Solutions of Coloured Salts in Hollow Prisms"; "On the Use of the Prism in Qualitative Analysis" (1857) He shows that when a coloured acid and base combine, a solution of the salt so formed only allows those rays to pass which are not absorbed by either constituent separately. He taught us the optical detection of didymium in the same year, and also studied the influence of heat on the colour of saline solutions, showing that whilst in some cases the intensity only of the colour was altered, in others the tint was completely changed. In 1860 he published a useful paper on the use of the polariscope in chemical investigation. Of his other papers on physical subjects, the following may be mentioned:—"On the Connection between the Optical Behaviour, Specific Gravity, and Chemical Composition of Ethereal Oils"; "On the Refraction Equivalents of some Elements"; "On the Refraction and Dispersion Equivalents of Chlorine, Bromine, and Iodine"; "On the Refraction Equivalents of Carbon, Hydrogen, Oxygen, and Nitrogen"; "On the Specific Refraction and Dispersion in Isomeric Bodies"; and (with Dr. Perkin) "On the Relation between Molecular Magnetic Rotation and the Refraction and Dispersion of Nitrogenous Compounds."

One of Dr. Gladstone's most important investigations was the determination of the refractive equivalents of many of the metals. The object was not, however, only to determine these equivalents, but also to answer the question whether any of the elements possessed more than one refractive equivalent. As the refractive indices of the metals could not, on account of their opacity, be directly determined, he operated upon solutions of their salts, first proving, in cases where both solid and solution were available, that the refraction was the same in the solid and in its solution, whether the solvent was aqueous or alcoholic, and whether concentrated or dilute. As the refraction equivalents of all sodium compounds were between 3 and 3·9 less than the corresponding potassium compounds, it was proved that the electro-negative constituent of the salt had the same optical effect no matter with what metal it was combined By taking the refractive equivalent of potassium as 8, and dividing it by the atomic weight (39) of potassium, he obtained for the specific refractive power of that element the number 0·205, and by a similar series of determinations the specific refractive power of sodium, lithium, magnesium, barium, strontium, calcium, zinc, nickel, cobalt, lead, and mercury were ascertained.

BUCHANAN MEDAL.

Sir John Simon, F.R.S.

The Buchanan Medal is presented to Sir John Simon, who may fairly be termed the founder of modern sanitary science.

When, in consequence of the appalling facts relating to the condition of the indigent classes in London which were brought to light by the Sanitary Commission of 1843, powers were conferred by the Legislature on the Corporation for the improvement of so much of the metropolis as is under their control, John Simon was appointed Medical Officer of Health of the city. In this capacity he brought into existence a system of sanitary administration which has served as the model on which similar systems have been organised, not only in Great Britain, but throughout the civilised world.

When, in 1858, the powers of the General Board of Health were transferred to the Privy Council, the knowledge and experience gained by Mr. Simon during his seven years of office in the city were made available for the country at large by his appointment as Medical Adviser of the Government. He held this office for fifteen years, during which he not only energetically and effectually promoted measures of sanitary improvement both in town and country, but initiated a system of scientific investigations to be conducted year by year at the public expense, and it is deeply to be regretted that his plans were not fully carried out.

The funds for this medal were supplied by Sir John Simon's late distinguished pupil, Dr. Buchanan, and it is fitting that the first award should be to the master.

[We are glad to be able to reproduce the portraits of the Royal, Davy, and Buchanan medallists. The portrait of the Copley Medallist, Prof. Albert von Kölliker, will be given on a subsequent occasion in connection with an account of his life and work.]

Report of the Council.

Many of the subjects referred to by the President in his Address at the last anniversary have continued to engage the attention of the President and Council during the past year.

Among the most important duties discharged by the Council is that connected with the consideration of papers communicated to the Society, with a view to ultimate publication in the *Philosophical Transactions* or *Proceedings*. In this duty they have received the most valuable assistance from the Sectional Committees, which were appointed under the Standing Orders mentioned in the last Presidential Address, and which now present a record of their first complete year of working.

In all 116 papers were received between the close of the Session, 1896, and the corresponding period in 1897. Of these, 37 were submitted for publication in the *Philosophical Transactions*, and 70 in the *Proceedings*; and 23 and 75 have been ordered for publication in the two categories respectively.

During the past year 22 papers have been published in the Mathematics and Physics section, and 10 in the Biological section of the *Philosophical Transactions*. The two sections together contain in all 1312 pages of letterpress and 22 plates. Nineteen numbers of the *Proceedings* have been issued, containing 991 pages and 9 plates.

A meeting for discussion in accordance with the regulations contained in the Standing Orders adopted last year was held in March of the current year. The discussion was based on a paper contributed by Sir Norman Lockyer "On the Chemistry of the Hottest Stars"; this, together with some of the principal contributions to the discussion, has been printed in the *Proceedings*.

In pursuance of the resolution of the International Conference on a Catalogue of Scientific Literature, the Council at the beginning of the Session, upon receiving the report of the British delegates to the Conference, and in accordance with the 26th resolution of the Conference, viz.:—

> (26) "That the Royal Society be requested to form a Committee to study all questions relating to the Catalogue referred to it by the Conference, or remaining undecided at the close of the present sittings of the Conference, and to report thereon to the Governments concerned,"

appointed a Committee with full executive powers. This Committee has since been engaged in developing a scheme for the preparation of the projected complete Catalogue of Scientific Literature.

The Committee has held a number of meetings, has devoted much time to the discussion of the difficult questions which arise in devising methods for carrying out so large a scheme as that contemplated by the Conference, and has appointed a number of special Sub Committees for drawing up schemes of classification for the several branches of science.

In view of the resolutions of the Conference, it appeared desirable to establish a (provisional) British Catalogue Committee, which might be consulted by the Committee of the Royal Society on questions relating to the collection and preparation of the material supplied by the scientific literature of Great Britain and Ireland, and might ultimately develop into the National Bureau for the United Kingdom contemplated by the Conference.

An appeal was, therefore, made by the Royal Society's Committee to the chief Societies representative of the sciences to be included in the Catalogue, and to certain important libraries, requesting the appointment of representatives.

Excepting in two cases, in which the nominations are delayed, all the societies and libraries applied to nominated representatives as requested.

At the first meeting of the British Committee thus constituted, representatives of nearly all the sciences included in the invitation attended, and expressed the willingness of the bodies they represented to co-operate in the work of the International Catalogue, though in some cases it was stated that they would not be able to contribute towards the expenses.

The further action to be taken by the various societies towards carrying out the work indicated above, will be considered by committees specially appointed by them for the purpose, and will form the subject of reports to be made to the British Committee.

With the object of keeping the delegates to the International Conference informed as to the work of the Committee, and of eliciting from them suggestions and criticisms upon the matters still under discussion, an *ad interim* statement of the progress so far made in its deliberations has been sent confidentially to all the delegates.

Progress continues to be made with the "Catalogue of Scientific Papers" and with the classified Index thereto.

As regards the supplementary portion of the Catalogue, the transcription of the copy is now approaching completion, and the Council hope that the first instalment of copy may be ready for the printer early in the new year. During the year ending on October 31, about 130 serials have been indexed for the purposes of the Catalogue, representing approximately 774 volumes, and involving the transcription of about 41,000 titles.

Of the classified Index to the Catalogue, about 275,000 slips have now been prepared, of which about 100,000 have been translated. An experimental classification of these slips is being made, in the course of which about 53,000 have already been classified under the eleven divisions sanctioned by the Catalogue Committee. During the past year about 65,000 slips have been prepared, of which about 13,000 have been revised, or translated, as occasion required.

Under the regulations for the administration of the Government Grant Fund, the Council have, upon the recommendation of the Government Grant Committee, made grants amounting to 3115*l.*, in addition to a grant of 1500*l.* made to the Joint Permanent Eclipse Committee out of the Reserve Fund towards the expenses of observing the approaching solar eclipse.

Early in the year, the Council appointed a Committee, called the Government Grant Review Committee, to report upon the manner in which the grants made from the Government Grant have been expended, and on the scientific results thereby attained. The Committee has met, but has not yet reported to the Council. The question of the reappointment of the Committee to make an annual report on the subject referred to them is under consideration.

The Report upon the results of the expedition sent out last year, under the direction of a Committee of the Royal Society, to investigate the structure of a Coral Reef by boring, was presented to the Society in a paper which was printed in the *Proceedings* of February 18, 1897 (vol. lx. p. 502). In that report, the Chairman of the Committee expressed the opinion that a more successful attempt would probably be made from Australia, and the Council therefore heard with satisfaction early in March that the authorities at Sydney would probably be willing to renew the attempt at boring with some assistance in money and influence from the Royal Society. Later, the Council was informed that a second expedition had been despatched from Sydney with the assistance of the Royal Geographical Society of Australasia on the agreement that the core, when recovered, should be sent to the Royal Society, and that all scientific details of the results of the expedition should be reserved for the Royal Society to publish. On the recommendation of the Coral Reef Committee, the balance remaining in hand from last year's expedition was voted in aid of the Australian expedition.

Early in the present month, the Secretaries received a preliminary report from Prof. David, in which he informed them that on September 6 the boring had attained a depth of 557 feet, and in the lower part had pierced more than one mass of coral limestone, one—about 20 feet thick—ending at 550 feet; they have also been informed that the boring was continued after the above-named date, and was still proceeding in generally similar material to that above, at a depth of 643 feet.

The Joint Permanent Eclipse Committee has organised expeditions for the observation of the Total Solar Eclipse in January next; and, at the request of the Committee, applications have been made to the War Office for leave of absence for Capt. Hills, R.E., in order that he may take part in the observation of the Eclipse; to the India Office, for facilities for the landing of instruments free of duty; to the Admiralty, for the conveyance of one of the observing parties to and from their observing station in one of H.M.'s ships; and to the Colonial Office, for facilities for the transhipment of that party from a passenger steamer to the ship of war at Colombo.

All these requests have been acceded to by the authorities.

The Committee appointed last year at the request of Her Majesty's Secretary of State for the Colonies, to investigate the subject of the Tsetse Fly Disease in South Africa has, in the course of the year, through Drs. Kanthack and Durham, and Mr. Blandford, conducted a careful investigation into the disease so far as it can be studied in this country, in subjects inoculated from a dog sent over from South Africa by Surgeon-Major Bruce. The Committee have, at the same time, been in communication with Surgeon-Major Bruce, keeping him informed of the progress of the inquiry here, and offering him suggestions for further investigation in South Africa. The experimental investigations, under Dr. Kanthack, are being pursued at Cambridge, with the aid of a grant of 200*l.*, generously placed at the disposal of the Council by Mr. A. Beit for this purpose. A letter, however, has recently been received from the Colonial Office, stating that Surgeon-Major Bruce's investigations have, for the present, been suspended, and he himself has been directed to return to military duty. The investigations have, so far, not resulted in the indication of any practical preventive treatment of the disease, but the life-history of the hæmatozoon, discovered by Surgeon-Major Bruce and shown by him to be the essential cause of the disease, has been carefully studied, and still presents problems of great interest.

Acting upon the recommendations of the Scientific Relief Committee, the Council has during the year granted 545*l.* to assist scientific men or their relatives in distress. Early in the year the Council found it expedient to codify the practice and original regulations, which had been modified from time to time since the formation of the Scientific Relief Fund, in a series of regulations for the guidance of the Committee in the administration of the fund. The revised regulations will be printed in the new edition of the "Year-Book."

In January the Council received a letter from the Royal Society of Canada urging them to move the Government to give their adhesion to a scheme for the unification of time at sea by the assimilation of the astronomical and civil day, with a view to the necessary alteration being made in the *Nautical Almanac* for 1901. The Council appointed an influential committee to consider the question, and received from them the following report:—

"The Committee report that as there is a great diversity of opinion amongst astronomers and sailors as to the advisability of the adoption of civil reckoning for astronomical purposes, and as it is impossible to carry out such a change in the *Nautical Almanac* for the year 1901, they do not recommend that the Royal Society should at present take any steps in support of the suggested change of reckoning."

Acting upon this advice, the Council have for the present refrained from taking any steps in support of the suggested change of reckoning.

The biennial election to the Joule Studentship was, under the terms of the Trust, placed by the Council last year in the hands of the Académie des Sciences, Paris, which has conferred the award on M. Jules Perrin, Doctor of Sciences, of the École Normale.

Early in the year, the attention of the Council was called to the system of teaching natural science in schools, and a Conference on the subject was arranged between the President and Council and the Fellows appointed by the Society as members of the governing bodies of the public schools. At this Conference an interesting discussion on the subject took place, and a general expression of opinion as to the desirability of attaching increased importance to the teaching of science as a necessary element of education was recorded; but the Council has not at present decided upon taking any further steps in the matter.

About a year ago the President and Council were invited by the Council of the British Association to co-operate in approaching Her Majesty's Government with a view to the establishment of a National Physical Laboratory. At the suggestion of the President and Council, a Joint Committee was formed to discuss the question, and to take action in furtherance of the desired object. This Committee waited upon Lord Salisbury, and laid before him the arguments in favour of the scheme. As a result a Committee has been appointed, with Lord Rayleigh as Chairman, to consider the desirability of establishing such a laboratory, and is now sitting. This Committee recently invited the Royal Society to appoint one or two Fellows to give evidence before the Committee on the subject under reference, and the President and Council have accordingly invited Lord Kelvin and Prof. Oliver Lodge to undertake this duty, which they have accepted.

In May last the Council received a request from Sir Benjamin Stone to nominate representatives upon the preliminary Committee for carrying out a scheme for a National Collection of Photographic Records, and Prof. Lapworth and Prof. Meldola were accordingly appointed to serve on the Committee.

Occasion arose during the past year for the exercise of the functions assigned in 1885 to a Committee designated the Indian Observatories Committee, which, however, has been held to be not a Committee of the Royal Society. The Astronomer Royal having called the attention of the President and Council to the anomalous position of this Committee, it was decided to appoint a new Committee of the Royal Society, to be named the Observatories Committee, to advise the Council on any questions similar to those formerly referred to the Indian Observatories Committee.

Reports have been received from the Kew Observatory Committee (published in the *Proceedings*), the Water Research Committee, and the Meteorological Council.

The Library continues to grow, especially in the section of scientific serials, and, although two book-cases have been added in the saloon, the question of shelf accommodation must soon become a matter for serious consideration. During the past year 10 new serial publications have been added to the 440 which the Society already received at regular intervals by exchange or purchase. Of these 450 serial publications, about

46 are issued in monthly parts
14 ,, ,, weekly ,,
10 ,, ,, fortnightly ,,
10 ,, ,, quarterly ,,

and the remainder at irregular intervals.

Besides these, 53 complete books have been added to the library by presentation or purchase. Among these may be specially mentioned the first volume of the collected papers of the late Prof. J. Couch Adams, two further volumes of the collected papers of Prof. Cayley, Sir Joseph Hooker's "Journal of Sir Joseph Banks," Capt. Lyons's "Report on the Islands and Temples of Philæ," the Procès-Verbaux of the "Conference Internationale des Étoiles Fondamentales de 1896," and the completion of Helmholtz's "Physiologische Optik."

THE ANNIVERSARY DINNER.

In the evening the Fellows and their friends dined together at the Whitehall Rooms, Hôtel Métropôle. The dinner was the most numerously attended of all that have been held in connection with the anniversary meetings of the Society. After the usual loyal toasts had been proposed by the President, Sir John Evans proposed the toast of "Her Majesty's Ministers and the Members of the Legislature," coupling with it the name of the Duke of Devonshire, the Lord President of the Council. In responding, the Duke of Devonshire is reported by the *Times* to have spoken as follows:—

As this is the first occasion on which I have had the honour and pleasure of being present at one of these gatherings, I am not acquainted with the subjects to which the speeches on this occasion are expected to be addressed. But, before accepting the invitation of your President to respond to this toast, I took the precaution of entering into a little negotiation with him, in which I succeeded in obtaining the concession that, whatever happened, I should not be called upon or expected to make a speech upon scientific subjects; and I think the President will bear me out in the statement which I make, that, therefore, I may be dispensed from any attempt to follow Sir John Evans, who has so kindly proposed this toast, into any scientific analogies which he may have been able to discover between the evolution of the human body and the government of the country. In making this confession of incapacity to address you upon scientific subjects, I feel that I am only acknowledging the existence in my own person of a defect which appears to be almost inherent in those who have devoted themselves to the pursuit of politics. I doubt very much whether since the time of Bacon there has ever, with one exception which I will refer to in a moment, been a Minister of the Crown who has been capable of saying anything upon these subjects to an assembly composed of the leading men of science of the day, such as those whom I have the honour of addressing, in words which would be worth their attention. The solitary exception which I can call to my mind is in the person of the present Prime Minister, who, if he had not devoted his powers so vigorously to political and public affairs, would, without doubt, have been an eminent man of science, and who, even now, amidst all his numerous and important avocations, has been able to keep up a not inconsiderable knowledge of the progress and discoveries of many branches of scientific pursuits. Gentlemen, I believe that the divorce which apparently has always existed between the pursuits of politics and science in our country has not been so complete in the case of other nations. We are all of us acquainted with the names of men in many foreign countries who have been eminent in science, and at the same time have, to say the least of it, been conspicuous in politics. Whether that fusion of political and scientific pursuits has always been a success, I do not think is a subject upon which I am called on to enter at the present moment. But, at all events, with regard to our own case, I think it appears to be certain that the calls which the pursuit of politics makes upon the time and strength of any man who desires to attain success in that career are so severe as to leave but little residue for the equally increasing calls upon the strength and time of those who aspire to distinguish themselves in scientific pursuits. But, while I do not look forward to any immediate closer connection between the pursuits of politics and science, I am not by any means sure that in some time not very far distant some greater knowledge and acquaintance with at least the results of scientific investigation and inquiry and research may not come to be a necessary part of the equipment of some portion at least even of our Government. The recent discoveries of science and their practical results have had so profound an influence on the social condition of all the peoples of the world, uncivilised as well as civilised; they have had, and are having, so great an influence upon the industrial progress, and therefore upon the growth or decline of nations, that it is almost impossible that some knowledge at least of the results, if not of the methods, of scientific discovery should become almost as indispensable a part of the training of statesmen as the knowledge of the instincts, the passions, and the interests of the people to which their studies have hitherto been almost entirely, or at any rate mainly, directed. The question whether with advantage the State can more directly interest itself in the direction or assistance of scientific inquiry is one which I have no doubt has been frequently discussed amongst you and upon which, probably, there would be considerable difference of opinion even among those who are assembled here. That is a question which I have no intention of entering upon, but there is a less ambitious object—the object of making some of the main principles of science and a knowledge of the results at least of the discoveries of science more accessible to the main body of the people—which has occupied our attention in recent years. It is also an object which has occupied a greater share of the attention of other nations, and one which, in my opinion, will require and demand greater attention on our part in the future. I hope and trust that at no distant time Her Majesty's Government may be able to make proposals and submit measures to you bearing in some degree upon the subjects to which I have referred. Among these I may mention such subjects as that of the creation of a teaching University for the City of London. I should not say for the city, but for London itself; and for the whole country some reorganisation of its secondary education, which is the indispensable foundation of any progress towards higher scientific study. I myself entertain a strong conviction that these are subjects of far greater importance than a great many which excite much more general and widespread interest. But strong as my own conviction, or the convictions of my colleagues, upon these subjects may be, I am not here to hold out to you any sanguine hope that we shall be able to induce Parliament to devote to them the attention which these subjects, in my opinion, richly deserve. Certainly we shall not be able to induce Parliament to give them the attention which they demand and require unless we can create in the country a widespread public opinion of their importance and their necessity. I think that many of those I have the honour of addressing, who stand at the head of the scientific professions, may be able in these matters to render great assistance to the Government by guidance, counsel, or advice, and, by helping us, thus assist to create throughout the country a public opinion of the importance of these matters. I think you can assist us in bringing home to the minds of many who have hitherto given, perhaps, an incomplete consideration to these questions the fact that that country cannot prosper which neglects the prosecution of either the higher or the subordinate branches of scientific research, or which is indifferent to the scientific training of those who are destined in the near or even the more distant future to conduct the industrial and commercial enterprises of this Empire. I will not trespass further upon your time except to thank you in the name of my colleagues for the very cordial manner in which this toast has been proposed for your acceptance by Sir John Evans and for the manner in which you have received it.

The American Ambassador in rising to propose the health of the Royal Society, said:—I can only follow at a great distance the example set by his Grace the Duke of Devonshire, and apologise at the beginning for my lack of qualification to address such an assembly as this. I regret that I have not even that smattering of scientific knowledge which would enable me to put on an appearance even of saying anything instructive or amusing. The only reason why I do not stand entirely mute is that I am unwilling by silence to seem indifferent to the great compliment which has been paid me in assigning to me this honourable duty. It is in associations of men like this, in institutions like the Royal Society, and similar bodies in America, of course of more recent date and of narrower resources, that there exists one of the strongest bonds of union that unite the two great branches of our race. They are held together by a common love and pursuit of universal truth, by devotion to the highest interest of mankind, by a kindred passion for light and progress. In your pursuits there is everything that unites and nothing that divides. The results of science are all gain and no loss. The triumphs of war are bought by the tears and anguish of both sides. The success of diplomacy and trade are often attended by the discomfiture of one party. But the whole world is brightened and made more livable by the achievements of a Faraday, a Morse, or a Fulton. The genius of a Lister or a Morton lessens incalculably the whole vast sum of human suffering, and every invention or discovery on either side of the sea—the product of the patient, self-denying labour of any of the scholars of our race, whether it be Lord Kelvin or Edison, Bessemer or Graham Bell, Huxley, Tyndall, or Marsh—is at once thrown into the common stock of the world's intellectual riches, profiting every one and injuring none. It is for this reason that I—although I have no claim to sit among scholars or men of science—am glad to be allowed to come here and pay my humble tribute of profound respect to those eminent men who, under the auspices of this venerable institution, are doing so much to hasten the glad day when all misconceptions and misunderstandings, born of ignorance and prejudice, shall fade away in the light of dawning truth and widening knowledge; when, to use the language of your great poet, who was himself through life a patient and devoted student of science, "Universal Peace" shall

> Lie like a shaft of light across the land,
> And like a lane of beams athwart the sea.

I have the honour to propose the health of the Royal Society, and to couple with the toast the name, honoured and revered in every country upon earth where high genius, devoted to the loftiest purposes, is valued and appreciated—the name of Lord Lister.

The President responded, and afterwards proposed the toast of "The medallists," to which Prof. Forsyth replied. The dinner terminated with the toast of "The guests," proposed by Lord Kelvin, and responded to by Prof. Lewis Campbell.

USEFUL INSECT PRODUCTS.

THE commercial value of the insects from which cochineal, lac, and Japanese white wax are obtained were briefly referred to, by Dr. L. O. Howard, in the course of a short paper on a useful American scale insect, read at the last meeting of the Association of Economic Entomologists. It was pointed out that for many years the cochineal or cactus scale insect, now called *Coccus cacti*, was used as the basis of an important red dye, until practically superseded by the introduction of aniline dyes. In the same way the European Porphyrophora was used in the production of a purple dye. Aside from the dye insects, we have the lac insects, of which a single species, *Tachardia lacca*, produces practically all of the shell-lac, stick lac, and button lac of commerce. This species is Asiatic in its distribution; but in the south-west States, upon the very abundant creosote bush, a lac insect occurs in an enormous quantity, the commercial possibilities of which have not been developed. This is the congeneric species, *Tachardia larreæ* (Comstock). This insect has been known to science only since 1881, but was long prior to that time known to the Indians, who for many years have been in the habit of collecting the scale insects and forming them into more or less elastic balls, which their runners were in the habit of kicking before them as they journeyed from one point to another. There are other species of the same genus inhabiting North America. The third substance of commercial importance derived from scale insects is a pure white wax, which is secreted by the Chinese and Japanese *Ericerus pé-la* and by the Indian *Ceroplastes ceriferus*. On account of its expense, and on account of more or less available substitutes, this wax has not become of great commercial importance in Europe, but is much used in the Eastern countries, both in the making of wax-candles and in medicine. The Chinese wax is said to have ten times the illuminating power of other waxes. It is a beautiful wax, resembling beeswax in its chemical composition more nearly than the vegetable waxes, and is clear white in colour. Dr. Howard calls attention to the fact that in the far south-west of the United States there is a wax insect (*Cerococcus quercus*) which apparently needs careful investigation from the commercial point of view. Three species of oak are recorded by Prof. Comstock as offering food for this insect, viz. *Quercus oblongifolia*, *Q. undulata* variety *wrightii*, and *Q. agrifolia*. Dr. Howard recently received specimens of the insect from Mesa Grande, California. They were not sent in position on the twigs, but had been removed from the twigs, and compressed together by hand into a more or less pliable lump, somewhat resembling a lump of india-rubber, but not possessing the same elasticity. The substance, it is remarked, makes an admirable chewing gum, as it takes and retains flavours better than other gums. Part of it has been proved by chemical analysis to be a true wax, and part resembles rubber in its physical properties. The product is not only interesting from a chemical standpoint, but it may prove to be also of economic value, as the supply is well-nigh inexhaustible. By directing attention to these products of potential importance, Dr. Howard demonstrates the commercial uses of entomology.

THE RAINFALL OF SOUTH AFRICA.

A SHORT time ago the Meteorological Commission of Cape Town placed in the hands of Dr. Alexander Buchan the rainfall statistics obtained at 278 stations in Cape Colony during the ten years 1885–1894, in order that he might analyse and discuss them. Dr. Buchan has now completed his task, and the results are given in a publication just received from the Meteorological Commission. The report contains sixteen maps printed in different shades of blue to exhibit the rainfall in South Africa (from lat. 25° to 35° S.) for every month of the year, the maximum annual rainfall, the minimum rainfall, the mean annual rainfall, and the range of mean annual rainfall. All the information which the statistics are capable of affording has thus been extracted from them, and is shown graphically upon this series of maps.

In a brief introduction to the tables and maps, Dr. Buchan refers to a few points of interest to meteorologists and physiographers. It appears from this, and the map of mean annual rainfall, that the annual distribution over South Africa, to the north of the latitude of Clanwilliam, steadily increases from west to east, the amount on the Atlantic coast falling short of five inches a year, whereas on the east coast, for some distance to the north and south of Durban, it exceeds forty inches. From Philadelphia, a little to the north of Cape Town, all along the south and south-eastern coast (with the exception of a small portion from Cape Agulhas to Mossel Bay), and for some distance inland, the annual rainfall exceeds twenty inches. These southern slopes appear to be, longitude for longitude, the best watered portions of South Africa.

Dr. Buchan studied the statistics with reference to the sunspot period; and with reference to the subject reports as follows;—

Sunspot Period of the Rainfall.

"In order to see what connection may be between the sunspot period and the rainfall of Cape Town, the annual amounts are thus arranged:—

"Table showingthe difference of each year's rainfall from fifty-four years' average of 25·82 inches.[1]

Year of period	1	2	3	4	5	6	7	8	9	10	11
	in.	in.	in.	in.	in.	in.	in.	in.	in.	in.	in.
1842-43 ...	...	...	...	...	...	...	...	..	...	**·45**	·99
1844-54 ...	7·05	4·91	3·31	3·43	2·56	1·20	**7·66**	5·52	2·60	4·59	5·76
1855-65 ...	1·24	6·34	3·78	3·54	**10·91**	**3·31**	·36	**6·18**	·21	6·90	7·14
1866-76 ...	6·61	2·87	5·86	**6·82**	**2·24**	5·70	**8·51**	2·05	**·88**	·10	**·83**
1877-87 ...	**9·75**	**15·21**	7·07	8·11	·21	**3·49**	**6·24**	**2·47**	**2·10**	**2·08**	2·74
1888-94 ...	**10·24**	**5·16**	**·52**	**4·48**	**15·10**	2·40	3·27	...	...	..	...
Means ...	**1·02**	**1·25**	4·90	·42	**5·10**	**·50**	**2·75**	**·27**	·08	1·82	3·16
Means Bloxamed	·30	**·88**	1·36	·07	**1·73**	**2·78**	**1·17**	**·98**	·54	1·69	1·32

"The individual years' rainfall shows sudden transitions in amount from year to year. Thus 1877 and 1878 show respectively 9·75 inches, and 15·21 inches of excess above the average; whereas the two following years, 1879 and 1880, show 7·07 inches and 8·11 inches of deficiency. These two pairs of consecutive years are, further, the greatest departures above and below the average annual rainfall of the whole fifty-four years.

"The means of the eleven-year period have been 'bloxamed' thus, 1st year $= \frac{11+1+2}{3}$, 2nd year $= \frac{1+2+3}{3}$, and so on. The smoothed curve thus obtained is a remarkable one. The rainfall is above the average in the fifth, sixth, seventh, and eighth years of the sunspot period, but under the average in the other years. The curve further shows two maxima and two minima. The smaller maximum occurs on the first year, thence the rainfall diminishes to the smaller of the two minima on the third year; then gradually rises to the principal maximum, 2·78 inches above the average, on the sixth year; and thereafter steadily falls to the principal minimum, 1·69 inch below the average, on the tenth year. There is thus a difference of 4·47 inches between the annual rainfall of the wettest and driest years of the sunspot period. The steadiness of the increase and decrease of the rainfall during the period is the most remarkable feature of the curve. It must, however, be noted that the extreme irregularity of the annual amounts from year to year cannot be said to hold out a hope that the cycle can be turned to practical account in forecasting dry and wet years."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Mr. F. Harrison (New Coll.) has been appointed Examiner in Mechanics and Physics, Mr. W. W. Fisher (C.C.C.) in Chemistry, and Mr. C. H. Barks (Camb.) in Botany, for the preliminary examination in the Final Honours School of Natural Science.

Convocation has directed that 600*l.* a year be paid to the Visitors of the University Observatory for its use for the next five years, beginning January 1, 1898.

The following grants have been made to the Botanical Department: (1) for the Herbarium, Library, and Museum such a sum as will, with the Fielding Fund, make up 400*l.* a year; (2) 650*l.* a year for the Botanic Garden. The grants extend over the years 1898–1900.

The Professor of Chinese, James Legge, died on Monday at his residence in Oxford.

Mr. J. O. Griffiths, of Llandovery College, has been elected to a Mathematical Scholarship, and Mr. O. T. Falk, of Rugby, to an Exhibition at Balliol College. Mr. E. W. Shobridge, Bradford Grammar School, has been awarded a Mathematical Scholarship at Queen's College, and Mr. F. R. Sandbach to one at Corpus Christi College. At Hertford College, Mr. H. A. Brown, of Plymouth College, has obtained a Mathematical Scholarship, and Mr. R. Cambridge an Exhibition.

Mr. G. Priestley, of Eton College, has been elected to a Natural Science Scholarship, and Mr. S. Douglas, of Wyggeston School, Leicester, to an Exhibition at Christ Church.

THE Russian Government has granted 400,000 roubles for the construction of a chemical laboratory at the Polytechnic Institute at Riga.

A COURSE of ten Thomson Lectures on Magnetism will be given at the Free Church College, Aberdeen, by Prof. J. A. Ewing, F.R.S., from December 9-22.

DR. F. STANLEY KIPPING, F.R.S., Lecturer and Assistant in the Chemical Research Laboratory of the Central Technical College, has been appointed to the Professorship of Chemistry in University College, Nottingham.

PRESIDENT SETH LOW, at the request of the trustees of Columbia University, has withdrawn his resignation, which was presented before the election in order to leave him unembarrassed in the canvass; he will, therefore, continue to preside.

WE learn from *Science* that the Technical Institute in Munich has been given by the Government 175,000 marks for enlarging the electro-technical laboratory, 150,000 marks for the erection of a laboratory for the agricultural station, and 170,000 marks for enlarging other buildings.

THE Root Hall of Science and the Benedict Hall of Languages of Hamilton College were dedicated a few days ago. The former, which cost 31,000 dollars, was the gift of Mr. Elihu Root, and the latter, which cost 30,000 dollars, of Mr. H. H. Benedict, both of New York City.

THE Council of the College of Preceptors have arranged a number of lectures to be delivered between January 4 and January 14, and visits to Educational Institutions, for teachers (especially Secondary Teachers), who will be in London at that period. Among the subjects of the courses of lectures are the principles of class teaching, by Mr. J. J. Findlay; and the teaching of science, by Dr. C. W. Kimmins. This course will have special reference to the Headmasters' Association's syllabus of physics and chemistry. An address on eyesight in relation to school life, will be given by Dr. W. S. Colman; and one on circulating school museums, by Mr. E. Howarth. There will also be an exhibition of geographical lantern slides, specially prepared for the Geographical Association, by Mr. B. B. Dickinson.

AT the annual meeting of the Scottish Association for the promotion of Technical and Secondary Education, held in Edinburgh on Saturday, the President, Lord Reay, delivered an address on the necessity of paying more attention in this country to organising and systematising technical education. In the course of his remarks he said that though the Victorian era had been rich in men of the highest scientific eminence, other nations not possessing men of equal eminence had enriched themselves by the teaching of the men who filled such glorious pages in our history. In chemistry, in physics, in electricity, in geology, in astronomy, the most illustrious names of Scotsmen and Englishmen could be mentioned, but when it came to the adaptation of their teaching in the school, in the workshop, on large landed estates, they had to go to Germany, to the United States, to Switzerland, and to Belgium. Our system of education ought to be worked on better lines. No spasmodic efforts here and there to form science classes, but technical schools which led to technical colleges, on a carefully graded system, were needed. The Education Department would have to determine clearly the lines of demarcation of the various forms of education which it would support. In the United States, Germany, France, and Switzerland, public money was ungrudgingly given to technical schools, and there was no reason why in this country there should be so much hesitation. The cause of the success and progress of continental industry was due to the keen sense of competition and to the widespread conviction that all production must be placed on a scientific basis. Science there was not considered as a luxury, but as a powerful agent of economic production. The sooner we realised that our very existence as an industrial nation was threatened the better.

---

[1] The heavy type indicates an excess or plus amount, and the light, a deficiency or minus quantity as compared with the mean.

THE opinions expressed by Prof. Priestley Smith in a pamphlet on the "Aims and Methods of Education" (Cornish Brothers, Manchester), just received, are accepted by the majority of people who have given thought to educational systems. The ordinary middle-class parent is content to know nothing about the efficiency of the instructors in the schools to which he sends his children. Happily, the times are not without signs of the growth of a healthy interest in the subject of rational education, and we welcome every publication which will encourage its development. All of us are of much the same opinion as regards the futility of learning by rote, and the truly educational value of a kindergarten system of education for the young. A kindergarten may be described as a place where children learn by natural instead of unnatural methods, and consequently acquire more real knowledge than by any other system. But not every school that is called a kindergarten justifies the title, for in many of these schools, as in many private schools for the middle-class, qualification to teach is often a secondary matter compared with local influence. The elementary school teacher must show himself qualified to teach before he can be recognised by the Education Department, but we have not yet reached the stage of educational progress when the master of a private school must produce similar credentials. When these anomalies are destroyed we may perhaps hope for the establishment of a rational system of education, for we shall then have the men to put it into effect. Prof. Smith says many hard but true things with regard to the classical veneer which effectually covers up natural tendencies in the public school. "The follower of nature," he remarks, "in education, adopts a different system. He believes less in books, which supply information ready cut and dried, than in mental exercises carried on in class by question, discussion, and demonstration. He helps the boy to observe and compare examples, to discover likenesses and differences, and to arrive at rules and principles by inferring them for himself. He aims at *self-training*, and studies the art of promoting it. He declares that this system arouses a greater activity of interest in the boy, and makes of his mind an instrument for observation and reflection rather than a storehouse." This is the system of education we should encourage, because it is the one which will most benefit the child, the country, and the race.

SCIENTIFIC SERIALS.

Bollettino della Società Sismologica Italiana, vol. iii. N. 3.—An electric seismoscope of double sensitiveness, by G. Agamennone.—An elastic pendulum for mechanical action, by C. Guzzanti.—Notices of earthquakes recorded in Italy (February 18–March 20, 1897), by G. Agamennone, the most interesting being those of distant, but unknown, earthquakes on February 19–20 and March 2.

N. 4.—The earthquake of Kishm (Persian Gulf) of the night of January 10–11, 1897, by G. Agamennone. A correlation of some records of a previously unknown earthquake obtained at European observatories between 9.15 and 9.32 p.m. (Greenwich mean time) on January 10, with an earthquake occurring at 9.30 (?) in the island of Kishm, but the times are too discordant to enable the velocity to be determined.—Summary of the principal eruptive phenomena in Sicily and the adjacent islands during the half-year January–June 1897, by S. Arcidiacono.—Condition of the central crater of Etna from the second half-year of 1895 to the first half-year of 1897, by A. Riccò.—Notices of the earthquakes recorded in Italy (March 20–April 27, 1897), by G. Agamennone, the most important being the Umbrian earthquake of March 21–22, the Roman earthquakes of April 3, the Lucano earthquake of April 16, and the Abruzzi earthquake of April 26–27.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 25.—"On the Geometrical Treatment of the 'Normal Curve' of Statistics, with especial Reference to Correlation and to the Theory of Error." By W. F. Sheppard, LL.M., formerly Fellow of Trinity College, Cambridge.

The object of the paper was, in the first place, to simplify and extend the treatment of normal correlation as expounded by Francis Galton and Karl Pearson; and in the second place to obtain general formulæ in the theory of error, and to apply them to questions which arise in relation to normal distributions and normal correlation. The method was, throughout, elementary, the use of the differential and integral calculus being avoided, though geometrical infinitesimals were to a certain extent employed.

Physical Society, November 26.—Mr. Shelford Bidwell, President, in the chair.—Mr. Rollo Appleyard read a paper on the failure of German-silver and platinoid wires. The mechanical defectiveness, and the consequent electrical instability of alloys used for electrical wires, may be discussed from two points of view: (1) as to the constitution and metallurgy of the alloy; (2) with regard to the subsequent treatment and environment of the wire. In stating the case, the author gives instances of the failure of German-silver and platinoid wire that have occurred among several thousands of resistance-coils distributed over widely different latitudes. In periods of time, varying from six weeks to several years after manufacture, the wire on some of the bobbins became brittle and broke, not only on the outer layers, but also within the coils. The towns where the faults appeared are all within the tropics, and included nearly within the isotherm of 25° C. Other coils, of nominally the same material, manufacture, and environment, have retained their original good condition. It follows that metallurgical differences exist between different samples of the same nominal quality of alloy. Examples are given to prove that failure sometimes occurs with platinoid through which no electricity has passed. Provided that the wire is good, the effect of environment is almost insignificant, *i.e.* the question is one of metallurgy, rather than of instrument-making. The author introduces a distinction in regard to brittleness. He discriminates between "primary" and "secondary" brittleness. "Primary" brittleness is characteristic of certain alloys (for instance, of gold-lead, or of gold-bismuth) from the moment of their solidification. But the brittleness of German-silver and of platinoid is of a different order; it is a subsequent phenomenon. "Primary" brittleness is thus an accident of birth, and "secondary" brittleness is a disease that develops with age and circumstance. The fracture of bad specimens of German-silver and platinoid shows patches of dark metal, crevices, and fissures. It may be supposed that, during the process of cooling, "liquation" occurs—the metals that first solidify, rejecting yet molten portions, as ice rejects foreign matter. Consequently, the strength of the final alloy varies from point to point of its mass, and in passing afterwards through the die, the weaker portions give way, and the general structure is loosened: moisture can then intrude through the capillary channels. At all fissures and crevices the electric current produces undue heating; this accounts for the failure of resistance-coils on arc-light and other circuits. As regards the protection of coils against moisture, paraffin-wax is of no use whatever; it is highly absorbent. Shellac varnish is greatly to be preferred. Ebonite does not seem to have any deteriorating effect, but it may be well to keep the alloys out of actual contact with it. In conclusion, Mr. Appleyard expressed a hope that British metallurgists would give electrical alloys special consideration. Already, British cable-manufacturers are importing thousands of tons, annually, of sheathing-wire from Germany; this is sufficiently to be regretted; he had good reason to know that instrument-makers were beginning to get the wire for their resistance-coils also from Germany. He had not enough experience of manganin to say whether that material would stand rough service in the tropics. Prof. Ayrton said the paper had raised the extremely interesting question of the permanency of metals used for resistance-coils. Some time ago he had immersed bare platinoid wires in running water in metal tanks, and the wires all broke into short pieces. He thought, at the time, this might be due to electrolysis. On another occasion he had found that by raising the temperature of platinoid to a dull-red heat in the air, by an electric current, any acquired faults in the wire were corrected, and the original resistance and flexibility were restored. Even when such metals are in good condition, the resistance temperature curve does not return upon itself; it encloses a loop, indicating two distinct values for resistance at each temperature. He had been told by Dr. Muirhead that coils intended for hot climates should be enclosed in air-tight metal cases. English manufacturers were still dubious in regard to manganin. In 1892 he had twenty coils of this material, each of a thousand ohms; the wire was silk covered. There were 2000 volts between the terminals. Their resistance had certainly not changed by 1 in 1000, although there was some amount of vagueness regarding the fifth figure, which might be due to molecular alteration, for they were heated more than was good for resistance coils. He confessed that this manganin had come from Germany. Dr. S. P. Thompson mentioned an alloy that was proposed in Germany under the name of "Constantin." He would like to know whether any information could be obtained as to the employment of cast-iron wire. It was a metal that in some respects commended itself. He had observed the failure of some German-silver coils, but he had generally attributed it to rough handling. Mr. W. Watson referred to the recent work done at the Reichsanstalt with regard to German-silver and platinoid. It was there found that all alloys containing zinc were liable to erratic change of resistance, and were unsuitable for standard coils. Moreover, even the slight amount of zinc introduced into manganin during soldering with soft solder robbed that alloy of its constancy. Silver solder, containing 75 per cent. of silver, should be employed for manganin. If Prof. Ayrton's coils were soldered with soft solder, that was sufficient to account for the change in the fifth figure. Shellac varnish was undoubtedly the best protection for coils. Absolute alcohol should be used as the solvent, and the coils should afterwards be heated for some hours at 140° C. If a heating-current was passed through German-silver or platinoid coils immersed in water, the general result was to produce brittleness.—Mr. Watson then described a thermostat which he had contrived for drying the coils after applying the shellac varnish. A hot-air oven contains a thermometer with a platinum contact at the 140° mark, and an 8 candle-power lamp. The thermometer is in circuit with a relay actuating a mercury-key for the 8 candle-power lamp. The key consists of two mercury-cups, and a corresponding U-piece of copper, inverted, one limb to each cup. It is important to keep the heating-circuit always made; for this purpose a 32 candle-power lamp is permanently connected between the two cups.—Prof. Perry then read a note on a question in thermo-dynamics, arising from correspondence that had taken place between himself, Prof. Ramsay, and Mr. Rose-Innes, with regard to a paper in the *Roy. Soc. Trans.* Mr. Rose-Innes replied.—The President proposed a vote of thanks to the authors, and the meeting adjourned until December 10.

Mathematical Society, November 11.—Prof. Elliott, F.R.S., President, in the chair.—The President briefly referred to the recent decease of Lieut.-Colonel J. R. Campbell, who had served on the Council, and rendered signal service to the Society by his liberal gift of 500*l.* to its funds.—The Treasurer gave an abstract of his report, and, in the course of his remarks, pointed out that the publications of the Society had of recent years grown to such an extent as to tax its utmost resources, and that, were it not for the help of the funds munificently established many years ago by Lord Rayleigh, and more recently by the late Lieut.-Colonel Campbell, the Society would be compelled to materially restrict its sphere of activity.—The ballot having been taken, the President announced that the gentlemen whose names were given in NATURE (October 21) had been duly elected to serve on the Council for the ensuing session.—The following communications were made: On an extension of the exponential theorem, by J. E. Campbell; the integral $\int P_n^2 dx$, and allied forms in Legendre's functions, between arbitrary limits, by R. Hargreaves; on the Poncelet polygons of a Limaçon, by Prof. F. Morley; the calculus of equivalent statements (No. 7), by H. MacColl; the character of the general integral of partial differential equations, by Prof. Forsyth; note on Bessel functions, by H. M. Macdonald.

Geological Society, November 17.—Dr. Henry Hicks, F.R.S., President, in the chair.—The geology of Rotuma, by J. Stanley Gardiner. The author described the relationship of the island of Rotuma (situated in lat. 12° 30′ S., long. 177° 1′ E.) to the adjoining isles. It is almost separated into two parts, which are united by a narrow neck of sand. The interior is composed of volcanoes, which have emitted lavas and fragmental rocks. Around the volcanic rocks are stratified deposits composed of sea-sand with volcanic fragments. These are partly denuded, and are mantled round by coral-reef and beach sand-flats. A remarkable cavern in the lava of Sol Mapii, with lava-stalactites, was described; there is a similar cavern in Au Huf Huf. An account of the prevalent meteorological conditions was also given. In an appendix by Mr. H. Woods, some of the rocks were] described. They consist of olivine-dolerites and basalts and associated fragmental rocks.—A geological survey of the Witwatersrand and other districts in the Southern Transvaal, by Dr. Frederick H. Hatch. After giving an account of the physical characters of the area, the author proceeded to describe the various rocks, referred to (1) the Karoo system; (2) the Cape system; (3) the Primary or Archæan system. The Archæan rocks protrude in a few places through the sedimentary beds, which form the greater part of the area, and consist of an igneous complex of rocks of varied composition. The Cape system is capable of division into five distinct series:—

UPPER BEDS.	Magaliesberg and Gatsrand series; alternating quartzites, shales, and lava-flows. 16,000 to 20,000 feet.
	Dolomite and cherts, thickly bedded. 6000 to 8000 feet.
	Black reef; a bed of quartzite and conglomerate, 20 to 50 feet, and Klipriversberg amygdaloid; a basic volcanic rock, 5000 to 6000 feet.
LOWER BEDS.	Witwatersrand beds; sandstones and conglomerate (in part auriferous). 11,000 to 15,000 feet.
	Hospital Hill series; quartzites and ferruginous shales. 8000 to 10,000 feet.

The Karoo formation is represented by the coal-measures of Vereeniging and the district south of Heidelberg, and by the measures of other coal-areas. They have furnished plants which Mr. Seward refers to in a note as being of Permo-Carboniferous age. The age of the Cape system is doubtful. The Upper beds rest unconformably on the Lower ones, and if the latter be of Devonian age, as has been inferred, the former may represent the Lower Carboniferous rocks. In the discussion which followed the reading of the paper, the President asked whether there was any fossil evidence to show the age of the beds under those of Permo-Carboniferous age. The unconformities were important, and might indicate that there were rocks in the area older than those of Palæozoic age. Would it not be better to avoid using the term "Primary" for crystalline rocks suggested to be of "Archæan" age? Mr. C. Dawson pointed out the great lithological resemblance of the specimens on the table from the Hospital Hill series to some of the fluviatile rocks of the English Wealden group; particularly to the lower beds of the Hastings sands and Ashburnham group. The Cape series, of course, was a much older formation and had suffered change, but the rocks of the Hospital Hill series appeared to have suffered least. Prof. Le Neve Foster said that he considered that all persons interested in gold-mining were much indebted to the author for his very valuable contribution to our knowledge of the geology of a great gold-bearing region. He desired information upon two points: (1) whether the conglomerate-beds on the southern side of the synclinal are as rich in gold as those which have been so largely worked on the north side; and (2) what surface-indications guide the prospector in searching for the outcrop of the beds. Is their existence indicated by quartz-pebbles on the surface, or by ferruginous outcrops, or what? In conclusion, he complained of the use by the author of the expression "mineralisation of the conglomerate"; he wished in season and out of season to protest against this use of the word "mineralisation" Mr. W. H. Merritt said that what he thought of special interest was the mode of occurrence of the gold in these conglomerates. He said that this showed that auriferous solutions may occur in a very unexpected manner, and in very unexpected places; and in confirmation of this he alluded to a locality in British Columbia where gold occurred, and was worked in deposits of cupriferous pyrrhotite containing virtually no free quartz and occurring chiefly in gabbro. The Rev. J. F. Blake and Dr. J. W. Gregory also spoke. The author, replying to the President, admitted that in describing the ancient crystalline rocks he had used the term "Primary" indiscriminately with "Archæan." He agreed that it would perhaps be better to discard the former, and to use the latter term in preference. With regard to the age of the Cape formation, he had pointed out in the paper that the Witwatersrand beds were probably correctly correlated with the Table Mountain sandstone, and that the latter was underlain by the Bokkeveld shales, in which characteristic Palæozoic (Devonian) fossils had been found. Replying to Prof. Le Neve Foster, he instanced the Nigel Mine as one that had been opened up in payable ore on the south side of the synclinal. There was nothing to indicate which of the conglomerate-beds might carry gold, short of taking samples for panning or assay. He saw no objection to the use of the word "mineralisation" to indicate a secondary impregnation with mineral matter. He was glad to find that Dr. Gregory confirmed him in the idea that the Dwyka conglomerate was a volcanic breccia, and consequently indicative of volcanic activity.—Observations on the genus *Aclisina*, de Koninck, with descriptions of British species, and of some other carboniferous gastropoda, by Miss J. Donald, of Carlisle. The author made some preliminary observations on the genus *Aclisina*, and considered it advisable to regard *A. pulchra* as the type of the genus, while the so-called *A. striatula* must be placed among the *Murchsoniæ*, and *A. nana* is placed in a new genus.

Entomological Society, November 17.—Mr. R. McLachlan, F.R.S., Vice-President and Treasurer, in the chair.—Mr. Selwyn Image exhibited male examples of *Pieris brassicæ*, with a black spot on the disc of the forewings. They were bred from larvæ found on *Tropæolum* at Lee, N. Devon, and six out of ten males showed this variation. He also showed a dark aberration of *Vanessa urticæ*, taken at Copthorne in Sussex, and two fine specimens of *Plusia moneta* taken at Valerian, near Balcombe, Sussex.—Mr. M. Burr exhibited three new species of Rumanian Orthoptera in illustration of a later communication.—On behalf of Mr. T. D. A. Cockerell, of Mesilla, New Mexico, two specimens of *Synchloe lacinia* from that locality were exhibited to show the remarkable forms of variation found in individuals occurring at the same time and place and on the same flowers.—Mrs. Nicholl communicated a paper on the butterflies of Aragon, and Mr. Burr a list of Rumanian Orthoptera.—Mr. Tutt read a paper entitled "Some results of recent experiments in hybridising *Tephrosia bistortata* and *Tephrosia crepuscularia*."

Royal Meteorological Society, November 17.—Mr. E. Mawley, President, in the chair.—Mr. R. H. Curtis gave the results of a comparison between the sunshine records obtained simultaneously from a Campbell-Stokes burning recorder and from a Jordan photographic recorder. The Campbell-Stokes recorder consists of a sphere of glass, four inches in diameter, supported in a metal zodiacal frame. A card being inserted in one of the grooves according to the season of the year, the sun when shining burns away or chars the surface at the points on which its image successively falls, and so gives a record of the duration of bright sunshine. The Jordan recorder consists of a cylindrical box, on the inside of which is placed a sheet of sensitive cyanotype paper. The sunlight, which is admitted into the box by two small apertures, acts on the paper, and travelling over it by reason of the earth's rotation, leaves a distinct trace of chemical action. In an improved pattern two semi-cylindrical boxes are used, one to contain the morning, and the other the afternoon record. The Campbell-Stokes instrument gives a record of sun heat and the Jordan instrument a record of sun light; and whilst it is probably true that, as a rule, the burning and chemical effects vary directly with the brightness of the sun's rays, yet it by no means follows that the conditions which will produce the most active chemical action must necessarily and always be those most favourable for burning. It has been the opinion of most observers that the photographic instruments yield a larger record than those of the burning type. In order to set the matter at rest the Council of the Royal Meteorological Society determined to institute a comparison between the Campbell-Stokes and the Jordan recorders, which should thoroughly test the capabilities of the two instruments, and at the same time afford trustworthy data for determining how far the records yielded by the one may be accepted for comparison with those obtained from the other. These simultaneous observations were carried out by Mr. E. T. Dowson, at Geldeston, near Beccles, and extended over a period of twelve months. The records were sent to Mr. Curtis for tabulation, who gave the results of his examination in this paper. After describing the methods adopted for the measurement of the records, Mr. Curtis drew the following conclusions from the figures: (1) In the case of the Campbell-Stokes instrument the records are capable of being measured with a very fair degree of accuracy. (2) The records of the Jordan instrument afford room for much greater difference of opinion as to what ought to be tabulated, and consequently measurements of the Jordan curves are open to considerably more doubt than are measurements of the Campbell-Stokes curves. (3) When the whole of the photographic trace which can be distinctly seen, but including portions of it which are decidedly faint, has been carefully measured, the amount will approximate sufficiently to that of the Campbell-Stokes instrument to allow of records obtained from both forms of instrument being compared *inter se*. From an examination of the records at other stations it appears that on some occasions the instruments have begun to record within thirteen minutes after sunrise, and has continued up to ten minutes before sunset. Mr. Curtis concluded his paper by calling attention to various defects in the adjustment and working of the instruments, and pointed out how these might be overcome. After the paper had been read, an interesting discussion ensued as to the merits of the respective sunshine recorders.

Linnean Society, November 18.—Dr. A. Günther, F.R.S., President, in the chair—The President announced that since the close of last session they had been so fortunate as to receive from Prof. G. J. Allman, a former President of the Society, a portrait of himself painted by Miss Busk, whose portrait of her late father was now hanging near it. It was an excellent likeness, and he was sure it would be highly valued. He moved that a vote of thanks be recorded for the presentation, and this was unanimously agreed to.—Mr. Alan F. Crossman exhibited photographs of a fasciated lily (*Lilium auratum*), on which some information was given by Mr. A. D. Michael.—Mr. R. Morton Middleton exhibited and made remarks on some ants received from Ephesus. These had been referred to in a previous communication as being made use of in Asia Minor for the purpose of holding together the edges of incised wounds by means of their strongly-hooked and sharp mandibles (*Journ. Linn. Soc., Zool.* vol. xxv. p. 405). The species was now identified as *Cataglyphus viatica*, Fabr. Mr. Thomas Christy gave some additional information resulting from inquiries he had made of foreign correspondents.—Mr. J. E. Harting exhibited a specimen of the great black woodpecker (*Picus martius*), lately received from Colonel W. C. Dawson, of Weston Hall, Otley, Yorkshire, where it had been shot in his presence by a friend on September 8. It was shown that this could not be the bird which had recently been lost from the Zoological Gardens, since the latter did not escape until October 9. Allusion was made to the numerous records of the occurrence of this species in England, some of which at least seemed worthy of credence, since the recorded specimens had been obtained, and were preserved in the possession of trustworthy persons. Mr. Howard Saunders expressed the opinion that there was no sufficient ground for including *Picus martius* in the list of British birds, as from its partiality for pine forests and its stationary habits, it was not likely to be a voluntary visitor to this country. The President remarked that the perfect state of plumage of the specimen exhibited was satisfactory evidence of its not having recently escaped from captivity; and that the late Lord Lilford, the year before his death (which occurred on June 17, 1896), had two black woodpeckers in his aviary in Northamptonshire, and in consequence of their ailing in health, had given them their liberty. It seemed possible that one of these might be the bird lately shot in Yorkshire.—Mr. J. E. Harting also exhibited in the flesh a hybrid pheasant and black grouse, which had been received that day from Shropshire. In appearance it precisely resembled a similar hybrid of which a coloured figure is given in early editions of White's "Selborne."—On behalf of Mr. Leonard Lush, of Stonehouse, Gloucestershire, three white partridges (*Perdix cinerea*) were exhibited, which had been shot by him on the Berwyn Mountains in Wales early in October last. It was remarkable that in the covey, which consisted of nine birds, no less than five of them were white, four only being of the normal colour.—Mr. Hamilton Leigh exhibited the skull of a red deer recently shot by him in Scotland, in which there was a singular distortion of the pedicel, resulting from an ancient fracture of the left temporal bone.—A paper by Prof. A. Dendy, of Canterbury College, N.Z., was read, on *Pontobolbos Manaarensis* (gen. et. spec. nov.), a problematical cushion-shaped marine object, measuring from 13 to 36 mm. in transverse diameter, found attached to rocks in shallow water in the Gulf of Manaar, of which he had received fifteen specimens among a collection of sponges sent to him by Mr. Edgar Thurston, Superintendent of the Madras Museum. The object was found to be concentrically laminated and to contain calcareous material, and a "ground-substance," the various microchemical reactions of which were carefully described, and which, if protoplasmic, yielded no traces of nuclear structures. Minute algæ were also detected, and in the deeper layers foreign particles in the form of sand-grains. The predominant component was found to be a dense feltwork of minute filaments, for the most part radially arranged and destitute of contents, which after prolonged study the author had come to regard as bacterial. Comparison was instituted between these filaments and certain Schizophyta, and between the entire object and certain calcareous algoid "pebbles," described by Murray, from Michigan and elsewhere, as also between it and the gigantic Rhizopod *Loftusia* (Carp. and Brady); and as an admittedly tentative conclusion, the author, anxious to record the existence of so remarkable an object, inclined to the belief that it may be a symbiote involving some gigantic rhizopod undetermined and a bacterial organism. Prof. Howes, in reading the paper, submitted some microscopic sections of the object which had been made at South Kensington from material sent him by the author. He pointed out that spicules apparently of sponges could be detected among the foreign particles; and remarked that to him and his colleagues at the Royal College of Science it appeared that while bacteria were present, algal filaments were overwhelmingly predominant, and that the evidence for the supposed presence of a gigantic rhizopod was exceedingly slender. In this criticism he was supported by Mr. George Murray, who had also examined the material, and who, after considering the comparison with the afore-mentioned "pebbles," put forward a suggestion of probable similarity to the algal "pseudomorphs" apparently parasitic on sponges, first recorded by Carter in the *Annals and Mag. Nat. Hist.* for 1878.—Mr. F. Chapman read a paper on *Haddonia*, a new genus of Foraminifera, from Torres Straits. He explained, with the aid of lantern-slides, that *Haddonia* is a calcareo-arenaceous type, of the subfamily *Lituolinæ* (of Brady).

CAMBRIDGE.

Philosophical Society, November 22.—Demonstration of the influence of uranium rays upon the formation of clouds, by Mr. C. T. R. Wilson. The effect was clearly seen by the members of the Society present.—Exhibition of models of the regular and semi-regular solids, by W. W. Taylor. Mr. Taylor exhibited and explained the construction of a large number of solids, the star solids having very various forms.—Partial differential equations of the second order, involving three independent variables and possessing an intermediary integral, by Prof. Forsyth. The author discussed the theory of these equations and developed it to the same extent as the corresponding theory in the case of two variables had already been developed. In particular, he dealt with the equations which are the extension of the Monge-Boole form; and he obtained a class of equations which is the generalisation of the class discovered by Goursat: they possess an intermediary integral, though not of the general functional character appropriate to the Monge-Boole equation.—The harmonic expression of the daily variation of solar radiation, and the annual variation of its coefficients, by Mr. R. Hargreaves.—On the fifth book of Euclid's elements, by Dr. M. J. M. Hill.—Electrification of newly prepared gases, by Mr. J. S. Townsend. This paper contained an account of experiments which were applied to find the charge on the individual carriers of the electricity in charged gases, and also the velocity of the carrier when acted on by an electric force. The results of experiments on diffusion show that the charge will not diffuse through porous earthenware with the gas.—On a chemical effect produced by the impact of kathode rays, by Prof. J. J. Thomson and Mr. Skinner. Aluminium is rapidly evaporated from the kathode by an electric discharge in a highly exhausted vacuum tube in which air has been replaced by mercury vapour. The metal is condensed over the walls of the tube in the form of a bright mirror. An iron kathode gives a similar mirror in a mercury vapour discharge tube. When the aluminium coating is dissolved off the wall of the bulb by hydrochloric acid a gelatinous membrane remains which gives the reactions of silica. When potassium vapour is used the glass opposite the aluminium kathode is roughened. In parts sheltered by screens from the discharge the glass is not attacked. In potassium vapour the aluminium kathode is not evaporated to any marked degree. Opposite the kathode both in the mercury vapour and potassium vapour bulbs a dark annular stain of the shape of the kathode is formed. This stain resists the action of strong hot hydrochloric acid, nitric acid, aqua regia and potash solution. The action of hydrochloric acid removed it apparently by dissolving the glass. The tests indicate carbon, but the quantity of the stain is too small to make certain. The stain is also formed on screens of mica, quartz and calcite. Monatomic gases appear to permit the evaporation of aluminium, as Prof. Callendar has observed its evaporation in an argon vacuum tube.—On the effect of zinc and other metals on a photographic plate, by Prof. J. J. Thomson. In the course of a discussion at the Cavendish Physical Society on Dr. Russell's paper on the photographic effect produced by certain metals, Sir George Stokes suggested that possibly light might be thrown on the question as to whether these effects were due to radiation or to the vapour of the metals, if photographs were taken with a stream of air flowing between the metal and the photographic plate. In consequence of this suggestion a series of the photographs made by zinc and amalgamated zinc (1) with nothing but air between the zinc and the photographic plate, (2) when the zinc was covered with a film of celluloid, were taken both with and without an air blast. The photographs with the air blast were found in both cases to be distorted, which is in favour of the view that the effects on the photographic plates are due to the vapour of the metals.

MANCHESTER.

Literary and Philosophical Society, November 16.—Mr. J. Cosmo Melvill, President, in the chair.—Mr. Joyce showed a small pocket form of voltmeter of the permanent magnet class. It is contained in an old-fashioned watch case, the first example having been made by Mr. Joyce in 1885. The present instrument is wound to read to three volts, a reading much required in a cell tester for users of secondary batteries. In order to make the case quite smooth outside, the terminals are formed of two spring chucks contained inside the instrument and capable of gripping any wire from No. 24 to No. 18 B.W.G. Instruments have been made reading to 120 volts total.—The President communicated a paper by Mr. Peter Cameron, entitled "Descriptions of two new species of *Mutilla* from South Africa," the specimens being exhibited at the meeting.

PARIS.

Academy of Sciences, November 22.—M. A. Chatin in the chair.—On the Leonids, by M. J. Janssen. No special increase above the ordinary number of shooting stars was observed on the night of November 13–14, either in Paris or at San Francisco. It is suggested that next year arrangements should be made to secure, if possible, the spectra of some of these bodies.—On the automatic registration of the calorific intensity of the solar radiation, by M. A. Crova. Two self-registering instruments of the pattern previously described when placed side by side yield identical curves. Owing to the delicacy of adjustment, however, this class of instrument is only suitable for an observatory, the necessity for a more portable type leading to the construction of the instrument described in the present paper. This consists essentially of a thermo-electric couple, in circuit with a self registering aperiodic galvanometer. The practical trials of this actimometer at the Meudon Observatory, and on Mount Blanc, have been quite satisfactory.—On certain questions relating to the problem of Dirichlet, by M. A. Liapounoff.—On completely orthogonal systems in any space whatever, by M. G. Ricci.—On the theory of infinite transformation groups, and the integration of partial differential equations, by M. Jules Beudon.—On a method of registering photographically thermal radiations, by M.

A. Guébhard. Five illustrations from photographs accompany this paper, by which it is shown that substances whose temperature differs but slightly from that of the atmosphere may be made to produce effects upon a sensitised plate. These results show that the phenomena described by some authors as photographs of human effluvia are simply due to the temperature of the hand. —Influence of temperature upon the rotatory power of liquids, by M. Ph. A. Guye and Mdlle. E. Aston. Primary amyl alcohol appears to offer an exception to the rules formulated in previous papers for the relation between rotatory power and temperature, inasmuch as in the neighbourhood of the boiling point the specific rotation undergoes a sudden increase. An explanation of this was sought in the observations of Ramsay and Shields, which showed that liquid amyl alcohol is composed of complex molecules, breaking up into single molecules on vaporisation. To confirm this, observations were made of the rotation of amyl alcohol in water and in benzene solutions, cryoscopic determinations showing that the alcohol was not associated in water, but polymerised in benzene. The results were exactly in accordance with the above hypothesis.—On the rotatory power of polymerised bodies, compared with their monomers, by M. Berthelot. Remarks on the preceding paper.—On chlorocyanamide, by M. Paul Lemoult. A thermochemical paper.—Contribution to the study of nitrification in soils, by M. Th. Schlœsing, jun.—Influence of oxygen and other substances upon the formation of chlorophyll, by M. W. Palladine. By placing etiolated leaves containing practically no carbohydrates on the surface of certain solutions and exposing to light, it was found that saccharose, raffinose, glucose, fructose, maltose, glycerine, galactose, lactose and dextrine distinctly favour the production of chlorophyll; inuline and tyrosine are without sensible action; whilst other substances, such as mannite, dulcite, urea, alcohol, retard or even prevent completely the formation of the colouring matter. —On certain improvements to the Bourdon anemometer, by M. R. Mailhat.—An apparatus to determine in a precise manner, by means of the X-Rays, the position of projectiles in the cranium, by MM. Remy and Contremoulins. The skull is photographed successively by two Crookes' tubes placed in different positions, and the trace thus obtained projected on to the head by cranial compasses.—Remarks by M. Marey on this apparatus. In eleven preliminary experiments on the dead subject, the exact position of bullets, and even of splinters of bone, was determined with perfect accuracy. Two cases on the living subject were also carried out with complete success.

DIARY OF SOCIETIES.

THURSDAY, DECEMBER 2.

LINNEAN SOCIETY, at 8.—On the Anatomy of *Caudina coriacea*: Prof Arthur Dendy.—On some Desmids from the United States: W. West and G. S. West.——Exhibitions: Specimens of Galls of *Cecidomya*: Prof. J. B. Farmer.—An Egg of *Echidna*: Martin Woodward.

CHEMICAL SOCIETY, at 8.—Ballot for the Election of Fellows.—On Collie's Space-Formula for Benzene: Dr. F. E. Matthews.

CAMERA CLUB, at 8.15.—Photomicrography: Dr. Spitta.

FRIDAY, DECEMBER 3.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Permanent Way: its Construction and Relaying: Grote Stirling.

GEOLOGISTS' ASSOCIATION, at 8.—Notes on the Geology of the Stort Valley (Herts and Essex) with Special Reference to the Plateau Gravels: Rev. Dr. A. Irving.

MONDAY, DECEMBER 6.

SOCIETY OF ARTS, at 8.—Gutta-Percha: Dr. Eugene F. A. Obach.

IMPERIAL INSTITUTE, at 8.30.—The Mineral Resources of British Columbia and the Yukon: A. J. McMillan.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—The Sulman-Teed Process of Gold Extraction: H. L. Sulman and Dr. F. L. Teed.

VICTORIA INSTITUTE, at 4.30.—Paper by Rev. H. Lansdell.

TUESDAY, DECEMBER 7.

ANTHROPOLOGICAL INSTITUTE, at 8.30.

RÖNTGEN SOCIETY, at 8.30—Adjustable X-Ray-Tubes: A. A. Campbell Swinton.

ROYAL VICTORIA HALL, at 8.30.—Klondike: Dr. T. K. Rose.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Paper to be further discussed: On the Law of Condensation of Steam: Hugh L. Callendar, F.R.S., and John T. Nicolson.

WEDNESDAY, DECEMBER 8.

SOCIETY OF ARTS, at 8.—The Mining and Metallurgical Industries of Sweden as shown at the Stockholm Exhibition of 1897: Bennett H. Brough.

THURSDAY, DECEMBER 9.

ROYAL SOCIETY, at 4.30.—The following Papers will *probably* be read:—On the Densities of Carbonic Oxide, Carbonic Anhydride, and Nitrous Oxide: Lord Rayleigh, F.R.S.—On the Application of Harmonic Analysis to the Dynamical Theory of the Tides. Part II. On the General Integration of Laplace's Dynamical Equations: S. S. Hough.—A Note on some Further Determinations of the Dielectric Constants of Organic Bodies and Electrolytes at Very Low Temperatures: Prof. Dewar, F.R.S., and Prof. Fleming, F.R.S.—On Methods of making Magnets independent of Changes of Temperature, and some Experiments upon Negative Temperature Co-efficients in Magnets: J. R. Ashworth.—The Electric Conductivity of Nitric Acid: V. H. Veley, F.R.S., and J. J. Manley.—On the Calculation of the Co-efficient of Mutual Induction of a Circle and a Coaxial Helix, and of the Electromagnetic Force between a Helix and a Coaxial Circular Cylindrical Sheet: Prof. J. V. Jones, F.R.S.—On the Refractivities of Air, Nitrogen, Argon, Hydrogen, and Helium: Prof. W. Ramsay, F.R.S., and M. W. Travers.

MATHEMATICAL SOCIETY, at 8.—The Construction of the Straight Line joining Two Given Points: Prof. W. Burnside, F.R.S.—A Theorem concerning the Special Systems of Point Groups on a Particular Type of Base Curve: Miss F. Hardcastle.—A General Type of Vortex Motion: R. Hargreaves.

SOME UNRECOGNISED LAWS OF NATURE.

Some Unrecognised Laws of Nature. An Inquiry into the Causes of Physical Phenomena, with Special Reference to Gravitation. By Ignatius Singer and Lewis H. Berens. With illustrations. Pp. xvi + 483. (London: John Murray, 1897.)

"AT last, after years of patient plodding in dim regions, where the footprints are few and the pitfalls many, the time has arrived when we are enabled to place before the world of science the first-fruits of our explorations."

So say the authors, Messrs. Ignatius Singer and Lewis H. Berens, at the opening of the preface to a handsome volume of nearly 500 octavo pages, published under the above title by Mr. John Murray, and printed in good style by the printer to the University of Oxford.[1] A subordinate title tells us that it is "an inquiry into the causes of physical phenomena, with special reference to gravitation," and a cursory inspection shows that it is decorated with quotations from great writers and philosophers at the head of each chapter, and that it is altogether a most ambitious work, courting the widest and closest attention.

The present reviewer is not one to regard lightly the danger of summarily rejecting a germ of new discovery because it happens to conflict with orthodox opinions, nor has he failed to have borne in upon him the conviction that there are indeed many real laws of nature at present unrecognised, some unsuspected, others scouted, by contemporary science.

It is, therefore, in no spirit of levity that he finds it his duty to state not only that the present volume contains much that is plainly and simply trash, he has to state further that, so far as he has been able to judge, there is nothing in it of the slightest value from cover to cover.

The former of these statements it is easy to justify by quotation; the latter may very likely be considered by the authors as an unfounded individual opinion typical of the arrogance of every professed physicist with regard to any novel view of the universe which may be brought to his notice. It is, however, difficult to imagine what manner of men these authors can be, nor how it happens that writers so conspicuously ignorant of the elements of physics, beyond what they have culled from a superficial acquaintance with a few popular books, should yet think fit to overflow in a wordy and pretentious volume, controverting many of the best-established scientific truths, criticising lightly the acknowledged masters of science, and setting forth a quantity of false philosophy and misapprehended facts with a flourish as if a new *Principia* were being given to the world. Who, again, are the readers of such a book? It has been most respectfully received in some quarters. Can it be that the state of school education in England is such that any considerable number of men of letters or of philosophy, or any other branch of study, find themselves able to accept such a book as this as containing possibly as good and sound science as, let us say, Thomson and Tait? Neither work is by them really read; perhaps both works seem to them nearly on a par. Perhaps they think that since Thomson and Tait and Helmholtz and Newton are all adversely criticised in the work before us, it is very likely true that the pretended facts of our boasted science are all uncertain fictions, and that the authorised scientific version of to-day is little better than a mass of hypothetical dogma.

If any such suspicion is in the slightest degree possible among the members of so-called educated society, it means that we are, after all, not far away from the dark ages; the death of a comparatively few individuals would perhaps loosen the grip of the human race on the truths of science, and plunge us once more into pre-Galilean ignorance. It is to be wondered if there are not more than a few who would welcome the change.

If the book is really an isolated phenomenon, it is as insignificant as the customary production of those paradoxers who were so delightfully gibbeted years ago by De Morgan; but it has not the usual air of the work of the paradoxer: the first half, at any rate, may easily impose upon the unwary as being a serious and sober attempt to solve perplexing problems, and contribute to the progress of natural knowledge. Sober and serious in intention we doubt not that it is, we do not suppose that the authors are playing off a conscious and expensive hoax; but, without the slightest desire to be abusive, we must maintain our view that a very small ingredient of common modesty would have prevented their shouting out their ignorance to the world—would have withheld them, with their little pittance of popular knowledge, from "undertaking to write the whole body of physicks," as Montaigne has it.

However, it is only fair now that we give some idea of the scope of the book, and that we make from it some illustrative extracts, so as to justify the terms of strictly measured depreciation which we have been constrained to use in our attempt to estimate it truly.

The four great fundamental and universal laws of nature, according to Mr. Singer (we are told in a note at the end of the preface that the science and philosophy of the work are exclusively due to Mr. Singer), are Persistence, Resistance, Reciprocity, and Equalisation.

The law of persistence is thus worded: "All matter tends to persevere in whatever state it may happen to be, and to resist change"; merely a simple and vague parody of part of the first law of motion, but it is intended to be much more comprehensive, and to include among other things such a statement as the following: "All organisms have a tendency to preserve their structure, organs, functions, habits, and dispositions unchanged."

As to "Resistance," we are told that it is the same thing as Persistence, and constitutes its quantitative measure; so the law of resistance, if it were to be stated definitely, would become a part of Newton's second law. The authors, however, rather avoid definite statements, and prefer nouns in capitals or italics, as if such nouns were laws of nature. By "Reciprocity" seems to be meant something akin to the third law of motion, though that is not in the least understood by them; and by "Equalisation" is intended something like the second law of thermodynamics, viz. that unless a difference of state exists between two bodies, there is no activity or tendency to activity.

---

[1] We do not hereby intend to imply that the University of Oxford is responsible for, or cognisant of, the production; but we do think that some care should be taken not to let its imprimatur be even apparently affixed to such a book as the one before us.

Thus it may be admitted that the customary teachings of science have not been wholly thrown away upon Messrs. Singer and Berens; they have acquired some rudimentary notions from their perusal of popular expositions of science, but the amount of vagueness and inaccuracy with which they have contrived to shroud those notions is almost incredible except to those who take the trouble to read their book.

In the first place, they are careful to confuse their terminology, as the following explanatory notes testify:—

> "We use the terms force and energy synonymously, and in the sense of power or strength, and shall use either of these indiscriminately as the one or the other may happen to be most convenient (p. 49).
>
> "To us 'heat' means simply temperature." Work can be got from a body by either heating or cooling it, and it is the degree of difference of temperature that is important in connection with the mechanical equivalent of heat, not heat *per se* (pp. 86, 88).
>
> "Pressure is 'work,' and so is motion" (p. 106).
>
> "'Force' and 'mass' (or 'weight' and 'mass') are synonymous terms; two different names for one and the same thing." And yet the proportionality of weight and mass or of gravitation force and mass is put forth as a real fact of the Newtonian theory (p. 349).

In the second place, they ignore in detail the laws which they admit in general. For instance, on p. 77 occurs the following illustration:—

> "Two bodies attracting each other, the one with a force of 100 and the other with a force of 10, the stronger body would be pulled one-tenth and the lesser nine-tenths out of their respective positions."

And many other instances might be given of their entire misapprehension of Newton's third law.

There are many singular instances of what appears to be malevolent criticism, statements of the beliefs or usages of orthodox science which are utterly destitute of basis in fact. The following may serve as illustrations:—

> "Confining our attention to what are called the physical sciences, we still find the greatest possible differences in both language and conception. We have hydraulics and hydrostatics, mechanics, dynamics and pneumatics, electricity and magnetism, light, sound, and heat, and so forth; each separate branch of knowledge having its own distinctive theory and peculiar terminology not applicable to the others. It is like the confusion at the Tower of Babel. The workers in the different fields of knowledge cannot understand each other, therefore cannot commune with each other for the purpose of seeing whether the conclusions deduced from one group of facts agree with the conclusions derived in other fields of inquiry."
>
> "The close relation of the different phenomena embraced under electricity, magnetism, and galvanism is now well known, yet are they still treated as separate and distinct sciences."

On p. 39 it is asserted that Newton's pendulum experiments, whereby he proved that inertia and weight were proportional, were proofs of nothing whatever, being only equivalent to using first one balance and then another. And on p. 40 it is said that when Newton found that pendulum bobs composed of two different materials swung together if their centres of oscillation agreed, he must have adjusted their centres of oscillation experimentally by means of equal times of swing.

In other words, he was either a fool or a knave; the full-blown paradoxer would not have shrunk from the appropriate epithets. But our authors are more polite; they are good enough to say, "Our quarrel is not with Sir Isaac Newton, but with human frailty"!

> "The fixing of the absolute zero at -273° C. is based on the theory that at that temperature a body would practically be annihilated—a conclusion which in a previous chapter we have shown to be unwarranted by the facts"!

There is more about this absolute zero of temperature, which is evidently a bugbear, and is considered as nonsensical as absolute position or absolute truth; in fact, on the subject of thermodynamics generally the authors are naturally afflicted with wholesale ignorance, which they believe to be scepticism. "The action of the steam engine is generally attributed to heat," they say on p. 84, "and calculations are based as to the quantity of work to be got out of a heat engine on the supposed mechanical equivalent of heat," and they proceed to point out the errors in this view. It appears that "the true cause of the motion of the piston is a disturbed equilibrium, and consequent tendency to equalisation." "Heat is no more an entity than acidity or hardness or depth of colour." In fact the whole doctrine of energy is absurd.

> "The whole doctrine of 'energy,' with all its astounding and contradictory corrollaries, has not been deduced from any facts at all, but is begotten of those conceptions which have come down to us in unbroken succession from our primitive and ignorant ancestors. The facts have merely been distorted in order to make them fit into the mould of the prejudiced human mind."

After this they proceed to "deal with the error which has given rise to the doctrine of the dissipation of energy." "When estimating the efficiency or power of doing work of a body we do not measure the *force which is just necessary to arrest its motion* [as we ought to do, is implied], but that which actually causes it to move a certain distance; in which case there is bound to be a discrepancy, an apparent loss."

Joule's experiments involved also a fundamental error, "owing to his assumption that a certain weight descending a certain height in a certain time is the measure of its mechanical power."

> "Where he committed the error was that he assumed the whole power of the descending weight to have been expended in driving his mechanism, [but] to produce motion in the mechanism the weight had to be greater than the resistance of the latter, . . . The power of the weight was greater than the mechanical effect in his paddles, and hence *greater than the corresponding thermal effect*. But *by how much greater* Joule never thought of determining."

No, alas, he believed practically as well as theoretically that action and reaction were equal.

> "Instead of estimating the 'heat' produced by friction, and then dividing the assumed mechanical power by the number of heat units—as Joule did—he might have estimated the mechanical effect produced by 'heat,' and

> then have calculated the heat equivalent of work by dividing the calculated thermal units (which no doubt he would have assumed as being all converted into mechanical effect) by the resultant work expressed in foot-pounds. Manifestly he would, in the latter case, have given too high a heat value to the mechanical effects; just as in his actual reasoning he has given too high a mechanical value to his heat units."

And then in a footnote:

> "There can be no doubt that it was purely accidental that the latter process has not been adopted by Joule"!

If he had happened to make his experiments in this inverse way, the authors go on to say, the law deduced would be "that the heat energy of the universe is becoming every day more and more changed into mechanical energy."

> "Thomson's error was due to his acceptance of Joule's conclusions. Joule, in his turn, arrived at his fallacious conclusions by the double error, . . . and both these philosophers have shared in the fundamental error that 'energy' is a *something* which is transferred from one body to another. Thus do we see how fertile an erroneous conception is in producing error. . . . Verily, as Lord Bacon expressed it"—

Then follows a quotation about the tendency of the human mind to reject contrary instances—not without great and pernicious prejudice—"in order that the authority of those previous conclusions may remain unshaken."

But not only do they thus misapprehend matters of real physics: the authors also fail to understand even such simple popular phrases as Tyndall's "Heat a mode of motion," and criticise it as if "mode" meant "result": saying that if heat were due to motion, then equal weights of different substances falling from equal heights should manifest the same increase of temperature (p. 165), and they go on to say that experiments on this point would be desirable. The generation of heat, they say, is due to states or acts of coercion, and in one of the few modest sentences to be found in the book they confess, on p. 163, that

> "our own belief is that all bodies while in states of coercion [like compressed air] are constant sources of heating, but that the diffusion is equal to the rate of generation, and hence no sensible increase of temperature can take place."

Further on they recover from this unusual weakness, stoutly maintaining that what they call Tyndall's view of heat is quite wrong, "since heat is due to arrested motion, not to motion itself," and boldly asserting that the amount of heat generated by bodies falling from a height depends upon their hardness,

> "a quantity of water or mercury falling from a certain height would not generate as much heat as would a like quantity of, say, steel falling from an equal height."

It would be tedious to follow the authors through their wild statements concerning electricity and magnetism in detail: the following brief extracts must suffice.

> "The gold-leaf electroscope, consisting as it does of glass and metal, will be found to be analogous to an electric machine. Indeed, the principle of the instrument is not yet understood, and no attempt has been made to explain it" (p. 211).
>
> "The resistance of thin wires is less than the resistance of thicker wires of the same material, which is the opposite of what is currently believed to be the case" (p. 222).
>
> "The total resistance of 6 lbs. of copper, for instance, would be the same whether the 6 lbs. of copper were only a yard in length, with a corresponding diameter, or a mile long and correspondingly thinner."
>
> "Air is a most powerful electric, and when between the poles of a powerful electro-magnet partakes of the character of a viscous fluid."

Then follows a reference to the usual well-known experiment of moving or spinning copper between the poles, with the following note appended:

> "which shows that air is attracted by powerful magnets and held there with a firm grasp."
>
> "The distinction between electric and magnetic attraction is arbitrary, and no more philosophic than is the distinction between light and heavy bodies, hot and cold bodies, voltaic electricity and galvanism."

The distinction usually drawn between conduction and induction is asserted to be spurious. Heat electricity and magnetism are said to be identical, being all excited by friction. Magnetic attraction may just as well be called gravitation, since the only difference is that it is not necessarily in a vertical direction.

Thus we get led back once more to the subject of gravitation, and Newton's law is replaced by the following foggy statement.

> "Bodies attract each other in proportion to their different states of excitation, in proportion to relative mass, and inversely proportionally to the square of the distance and intervening resistance."
>
> "The point of attraction of the earth for bodies on its surface cannot be in the centre . . . for that would involve the assumption that the opposite half of the globe . . . exerts a force equal to that of the nearer half."
>
> "The theory that attraction is proportional to mass is not borne out by facts: attraction on earth is actually less where the diameter of the earth is greatest. If we turn to the heavens matters are even less satisfactory."

The astronomical determination of the mass of central bodies turns out on their view to be quite illusory.

With regard to "action at a distance," our philosophers find no difficulty whatever; they point out that air and water and other matter only obstruct the fall of bodies, wherefore, of course the less there is between bodies the better they can attract. They quote the usual extract from Newton's letter to Dr. Bentley, and add comments

> "in order to show why such luminaries of the human intellect were unable to see what to us seems as plain as the noon-day sun; and we trust to be able to show the reader that it was again the *ignis fatuus* of suggestive words and false concepts by which these great intellects were decoyed from the path of philosophy into the quagmire of metaphysical word-quibblings."

But now, towards the end of the volume, when the Newtonian theory is once more attacked, the authors fail to keep their mantle so strictly down, and the cloven hoof of the familiar old paradoxer becomes at length conspicuous.

> "This fact, that the planets do not fall into the sun notwithstanding the assertion that they mutually attract

each other, but, quite contrary to this theory, actually recede from the sun at regular intervals, is as yet an unexplained problem. In works on astronomy, however, the fact is generally glossed over, and it is made to appear as if the recessions were most satisfactorily accounted for. But on closer examination the supposed explanation turns out to be either mere rhetoric or a series of equations of abstract mathematical problems. Why, if sun and planets constantly attract each other proportionally to their quantities of matter, and inversely proportionally to the square of the distance, do they not fall into each other and all into the sun? The question is a perfectly legitimate one, seeing that every writer on astronomy has deemed it necessary to offer explanations. But these explanations are far from satisfactory, as we shall now endeavour to show."

And so they proceed ultimately to arrive at the conclusion that,

"while there is no doubt that the curvilinear motion of terrestrial bodies is due to the joint action of two forces, viz. the impelling force and the attraction of the earth, there is no evidence either direct or indirect that planetary motions are due to two such independent forces."

The ridiculous ideas capable of being formed by men of so-called education concerning the meaning and function of mathematical reasoning is illustrated on page 353, where it is said first that Newton's achievement was not what is usually supposed:

"Newton, however, has done nothing of the kind; nor has he even attempted to do so. What Newton did prove was the *proposition* that 'A body [acted on] by two forces conjoined will describe the diagonal of a parallelogram in the same time as it would describe the sides, by those two forces apart.' It is the truth of this mathematical proposition that Newton proved, and not that planetary motions are actually due to two such forces."

And then it is added:

"Abstract mathematical formulæ can never prove a fact in nature." All that mathematics can do may be illustrated by the case of a man sent to market with eighteenpence, who returns with sixpence, then on the hypothesis that he spent the difference on a dozen apples, mathematics enables us to calculate the price of each apple; or, given the price, it can find the number of apples bought.

Criticism of this sort is gravely printed. It appears to be literally true that many men, including a few schoolmasters, believe mathematics to be represented by schoolboy studies, and especially by "problems leading to simple equations with one unknown quantity."

In Section A, at Toronto, recently, Lord Kelvin implied, *en passant*, that a schoolboy in the very first month of his algebraical studies came across something which when developed led into the heart of the mathematical arcana; viz. when he came across the imaginary roots of a quadratic equation. No wonder that in Lord Kelvin's perspective quadratic equations are relegated in imagination to something like the first month of a boy's mathematical study; but, alas, many of us know boys of sixteen who have been for years at what schoolmasters call mathematics, and who have hardly yet arrived at quadratic equations. In the perspective of many a British school, trigonometry forms a sort of goal, and the elements of the differential calculus loom dim and gigantic in the far future. When feebleness of the kind quoted by the authors is believed to represent anything like mathematics, no wonder that practical men and others regard it with aversion thinly veiled by contempt.

But not only is mathematical reasoning lightly regarded by our authors, they differ from most of their species in treating experiment also in a slight and unsubstantial manner, which though by no means intended for disrespect really amounts to it. A number of experiments are quoted, some of them made apparently by the authors themselves, which if they were true would constitute some of the greatest discoveries of the century; but they are obtained in the most casual manner, as if, like the scientific hero of many novels, the authors had only to retire into a back room for about twenty minutes, in order to make the most momentous and fame-bringing discovery. We quote two instances.

"By heating a body it is made to weigh less: that is, not merely is its specific gravity lowered, but its absolute weight is less, and it regains its former weight on cooling" (p. 380).

"Our explanation of this is that, though cool to touch, the molecules are still in a state of excitation, and hence their lesser weight" (p. 383).

"Another experiment was made as follows. A glass tube sealed at one end was contracted in the middle. In the lower portion were placed about 10 c.c. of water, and in the upper portion a stick of dry potassium hydrate of about an equal weight, and the tube was sealed. After cooling, the tube was weighed and then turned upside down, so that the water could flow on to the potassium hydrate. The stick of potassium hydrate partially dissolved, and the solution crystallised. On weighing it was found to be lighter by about 20 mgr. On shaking the glass the crystals partially redissolved, and the tube became heavier; but after some time the crystals re-formed, and the tube weighed again less" (p. 384).

On pp. 397 and 401 we are told that inside the crust of the earth there is a neutral sphere or zone outside which bodies press inwards, but within which they press outwards, so that gravity at a certain depth in the earth is inverted and bodies press upward. So this naturally explains volcanoes,—in fact the earth, if cooled, might explode like a Rupert's drop (p. 402).

Matter from the interior, if it ever got above the neutral zone, would be found to be light instead of heavy, and hence it is that the dust of Krakatoa took so long to settle (pp. 400 and 407)!

After this we can be surprised at nothing, and so we go on to learn:—

That the axial revolution of the earth is due to the radiation of the sun, like the motion of a radiometer or of a sunflower.

That the real diameter of the earth's orb is 506,734, and not 8000, miles.

That by reason of its axial rotation the earth rolls on its own orb, pressing against the zone of neutral attraction, and thus effecting its annual journey round the sun like a coach-wheel.

That the sunspots are circumsolar planets with satellites, their apparently irregular shape being an easily explained optical illusion.

That the terrestrial seasons are caused by unequal solar attractions; and other extraordinary nonsense.

We will on these topics make only two quotations, though the exposition of the doctrines occupies several chapters.

> "Nobody will question that at a certain distance between sun and earth a body will be more strongly attracted by the latter than by the former, or by the former than by the latter, as the body may happen to be nearer the one or the other. In other words, nobody will question that the earth has its own field of attraction as against the sun; hence all that is within that field of attraction would form part and parcel of the mass. Now, the distance between earth and sun is at all times determined by their relative states of excitation, as before explained. Hence the earth may be regarded at any one moment as being kept at a certain definite distance from the sun, as if held there by ropes or bars. But the earth revolves, and in revolving meets with a greater resistance on the side nearest the sun than on the opposite side; hence there is greater retardation on the one side than on the other: from which follows the translation in orbit. The laws of rigid mechanics find, therefore, here application. The earth is drawn towards the sun, but cannot pass a certain line; *and this line is the rigid surface against which it presses.* To the eye nothing may be there impenetrable; but to the earth this invisible circle is like a hoop of adamant, against which it presses and along which it is rolling in space."

And this brief note:—

> "Prof. Helmholtz estimated the depth of the luminous envelope at 500 (!) miles. This estimate . . . is ludicrous."

Thus at length the lofty position appropriate to superior knowledge is fully assumed; and from pitying and apologising for Newton, rebuking and correcting Thomson and Tait for their fundamental errors, the authors proceed to laugh at an estimate by von Helmholtz.

Behold, a greater than these men has arisen; another still larger volume already in manuscript is threatened; and the natural philosopher of the twentieth century is to be Ignatius Singer! O. J. L.

PHILOSOPHY OF KNOWLEDGE.

Philosophy of Knowledge. By Prof. G. T. Ladd. Pp. xv + 614. (London: Longmans and Co., 1897.)

PROF. LADD, of Yale, is well known as an industrious writer on psychology, and upon philosophy regarded mainly from a psychologist's point of view. The present volume gives his Theory of Knowledge, and with some *naïveté* he claims for it "the treatment due to a pioneer work," and avows a "quite unusual interest" in its success. His method he characterises as a constant striving "to make epistemology vital—a thing of moment, because indissolubly and most intimately connected with the ethical and religious life of the age."

Most modern psychologists of note have definitely broken with that abstract and detached view of their science which would argue the question of the "origin" of knowledge within the limits of a narrow subjectivism, and which would assume that thereby the questions of nature growth and validity had received adequate solution. The present tendency of psychology is rather to offer itself as that specialist training which makes general metaphysic profitable, or, at any rate, to endeavour to set itself right with metaphysic, by an alliance based, perhaps, upon a compromise.

Of such a tendency Prof. Ladd is a representative. He puts forward a strenuous plea for an ultimate view of knowledge and reality which shall neither be subjective idealism nor crude realism, neither wholly dualism in one sense of that word, nor wholly monism in one sense of that word. He insists on the implication in the act of knowledge of what he not very happily calls "extra-mental" or "trans-subjective" reality, meaning that we apprehend that which is manifestly independent on our individual consciousness, and does not emerge in it as a a matter of course as the result of its own laws. He urges the claims of our feelings and our will to be satisfied equally as well as our thinking taken abstractly. He demands as a sort of postulate of faith that we take it that things are known in some sense as they are. The self, he holds, is known as it really is, thinking, feeling, and willing. And things are known as what will not always as we will, and by an analogical *saltus* as other will.

This is interesting speculation, but it is rather eclectic than original. Prof. Ladd would seem to be a pioneer only in the sense that we are at present fortunately free from *Erkenntnisstheorie* as it is too often understood in Germany. For he is something too well read in theories of knowledge which pass with undue freedom from psychology to metaphysic, and often approach perilously near to *ignoratio elenchi.*

It is in his criticisms that this influence, which constitutes, as we venture to think, the weakness of his work, makes itself apparent. Interlined with positive views as to the relation of faith to knowledge, of æsthetic and ethical value to reality, where Prof. Ladd obviously owes much to Lotze, or as to the relation of thought and reality to will, where Wundt's influence is manifest, there are offered an erudite though inconclusive history of opinion and a running fire of uncomplimentary comment upon Kant, Mr. Spencer, Mr. F. H. Bradley, and others. And the sympathetic insight of the successful critic is wanting to the Yale professor. The results, as well as the methods, of certain thinkers are agnostic or sceptical, and that must not be. And so a discursive appreciation of various points of their doctrine is put forth, which, *e.g.* in the case of Kant, ranges, with the exception of a suggestion as to the implication of will in the treatment of the second analogy of experience, entirely within the circle of commonplaces on the subject, and is altogether unconvincing to believers in the results of sympathetic interpretation. Again, in dealing with post-Kantian idealism, it is not its alleged panlogism which he criticises, as he might well have done from his Wundtian standpoint, but rather its general tone or points so truistic that any theory of knowledge must, and if not explicitly yet tacitly does, meet them.

The discursive and rhetorical style of the book would of itself tend to ineffectiveness in matters of criticism. It is often picturesque, and has many happy phrases; it sometimes rises to eloquence, and is always eminently readable. But it is singularly vague and elusive. And the volume needs condensation. H. W. B.

OUR BOOK SHELF.

Bau und Leben unserer Waldbäume. Von Dr. M. Büsgen, Professor an der grossherzoglich sächsischen Forstlehranstalt in Eisenach. Pp. viii + 230, mit 100 Abbildungen. (Jena: Verlag von Gustav Fischer, 1897.)

THIS comprehensive volume on forest botany, which is essentially on the same lines as the well-known text-books of Döbmer-Nobbe, Hartig, and Schwarz, gives an interesting account of the structure and physiology of forest trees. The introductory chapters are devoted to a general external survey of the tree, note being made of the various forms of buds and shoots, while the influence of their position and development on the habit of trees is clearly indicated. An interesting subject is touched upon in the annual and periodic rate of height-growth, and reference is made to the relationship that exists between the rapidity of growth in youth and the light-requirements of trees. With hardly an exception trees that are intolerant of shading grow with great rapidity when young (larch, birch, &c.), and are thus enabled to keep their crowns well above the level of those of competing species. Slow-growing species, on the other hand, are not prejudically affected by moderate shading (silver fir, beech, &c.). Were they otherwise they could hardly have survived in the mixed primæval forest, where the struggle for existence proceeded without interference from the woodman's axe.

An important section of the book deals with the annual wood-ring, the characteristics of which are so useful in aiding in the identification and in explaining the properties of timber. Although our knowledge of the causes that lead to modifications in the annual ring of trees has been much advanced of recent years, there are still many interesting problems awaiting solution, as, for instance, in the matter of eccentric growth. The explanations that are usually offered can hardly be said to be sufficient to account for the constant eccentricity that occurs on sections of wood taken from roots and branches, as well as from stems that have grown upon a hillside. And even after all that has been written by Sachs, de Vries, Krabbe, Hartig, Strassburger, and others, who will confidently say whether pressure, nutrition, physical exhaustion of the cambium, water, or heredity is the true cause of the difference that exists in the structure of wood formed early and late in the growing season?

After discussing the formation of duramen and the properties of timber—where, by the way, one misses any reference to the latest work of Roth in America and of Schwappach in Prussia—the author proceeds to an examination of the leaf and root. As was to be expected, a good deal is said regarding the many theories that have from time to time been advanced to account for the ascent of water in trees—so ably summarised up to date by Marshall Ward in his book on timber—and while greatest prominence is given to Strassburger's experiments, the work of Dixon and Joly receives appreciative recognition. A chapter on fruits, seeds, and seedlings completes a volume which, while designed chiefly for foresters, cannot fail to be of use to a larger public, and especially to students of botany.

WILLIAM SOMERVILLE.

Physiography for Advanced Students. By A. T. Simmons, B.Sc. Pp. viii + 483. (London: Macmillan and Co., Ltd., 1897.)

THIS book is a supplement to "Physiography for Beginners" by the same author, and for those who have mastered the earlier work it will furnish an excellent continuation course. Matter, energy, the air, the sea, and kindred subjects occupy more than half the volume, while the description of the different members of "the universe" and of the various natural laws relating to them, occupies the remainder.

Both terrestrial and celestial subjects are admirably dealt with, the explanations being clear and to the point, and the selection of illustrations, which number 218, leaves nothing to be desired. The experimental method so successfully adopted in the previous book has been adhered to as far as possible, though there is naturally less scope than before for this treatment. Another notable and praiseworthy feature is the large number of references to books and *Proceedings* of societies dealing with special branches of the subject, and it is much to be desired that advanced students should acquire the habit of utilising information of this kind.

At the end of each chapter is a series of test questions, which will doubtless be greatly appreciated by teachers. There is also a summary of the chief points of each chapter, which will be valuable if not misused; but there is possibly some danger of the less serious students confining their studies to these condensed statements.

We believe that the book will admirably supply the need which must have been felt by teachers and students under the new conditions created by the revised syllabus. In conjunction with the volume to which it is a supplement, it will also provide the general reader with a comprehensive view of the earth and its relation to other bodies in space.

Chemistry for Photographers. By C. F. Townsend, F.C.S. Pp. xviii + 158. (London: Dawbarn and Ward, Ltd., 1897.)

GREAT is the number of those who practise the art of photography at the present day, but how many of these are acquainted with the chemical reasons underlying the numerous manipulations which are performed? Every photographer, it does not matter how much or how little he employs his camera, should make himself familiar with, at any rate, the chief rudiments of this science, even if he does not wish to enter more deeply into details.

The book which we have before us gives the reader a concise and clear insight into the various chemical questions which come into the sphere of photography. The author has carefully drawn attention to the fact, that by good judgment, and by paying heed to the actions of various chemicals employed, the photographic plate can be made to give results far better than when such knowledge is lacking.

Not only is the chemistry of the photographic image, developers, reversal, intensification and reduction, printing, &c., clearly explained, but useful information is collected, bearing on impurities, recovery of residues, cellulose, resins, varnishes, &c. Curiously enough, no mention is made concerning the pros and cons of mounting solutions, an important question for those who wish their prints to last more than a year or two. Perhaps this subject will receive attention in a future edition.

The book should be read by all who wish to gain an insight into the chemical side of photography.

My Fourth Tour in Western Australia. By Albert F. Calvert, F.R.G.S. Pp. xxvii + 359. (London: William Heinemann, 1897.)

MR. ALBERT CALVERT has written much upon Western Australia, and has been generous in publishing his views and convictions as to the mineral resources of that Colony. He now informs his readers that the object of previous works was to advance the interests of the Colony, whereas in the present volume the subject is treated "entirely from a personal standpoint." Open confession is proverbially good for the soul, and by declaring that the book contains a narrative of personal impressions, intended to interest and amuse the public, Mr. Calvert leaves no room for doubt as to the purpose of his new publication. In keeping with this object, a number of illustrations of purely personal matters are included in the volume.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Astronomical Constants and the Paris Conference.

MANY objections have recently been raised—above all, in America—to the decisions of the International Conference that met in May 1896, at Paris, with the object of choosing a uniform system of fundamental stars and astronomical constants for the four great ephemerides of Berlin, London, Paris and Washington. The matter is of the greatest importance, inasmuch as it refers to the bases of precise astronomy, together with a general tendency of all science to a method of international discussion that, leaving free and autonomous all personal and local initiatives, bring workers in such agreement as is necessary for nullifying discrepancies and contradictions. Of such tendency we have the most comforting manifestations in the International Geodetical Association, in the Commission (also international) for unifying weights and measures, and in the similar meetings of scientific men of every nation for the electrical measurements, for meteorological services, for the photography of the heavens. Astronomy is, perhaps, among all physical sciences the one destined by its historical tradition, no less than by its present and future necessities, to second—nay, to promote and develop—the cosmopolitan tendency. The grand spectacle of the face of the heavens, ever before the eyes of all; the difference of phenomena according to the horizons, which carries with it the need of co-operation between the observers diversely situated with regard to the celestial sphere; in fine, the high and significant moral education that comes to astronomers from the continual contrast between the immensity of the heavens and the miserable narrowness of the limits traced out conventionally on the globe between one country and another; here are the causes through which a spirit superior to any narrow nationalism was soon breathed into our souls. Tycho Brahe, the proud Danish patrician, the founder of practical astronomy in the Renaissance, sings sternly—

> Omne solum forti patria est, coelumque
> Undique supra. . . .

And his name, with those of Copernicus, Kepler, Galileo and Newton, form a constellation that shines not more for the sky of Denmark, than for that of Germany, Italy, or England!

On the other hand, on the sentimental considerations of the solidarity of the human race, to which a great weight must always be given, other arguments of a more modest and more positive character rest and flourish; these comfort, and, if I do not deceive myself, put out of all reasonable doubt the necessity of imprinting on our science an international character. From the day in which Frederic William Bessel solidly constructed, on the admirable observations of James Bradley, the "Foundations of Astronomy," enriching with his teutonic analysis the product of the patient British ingeniousness, a new current of collaboration among astronomers of every country was opened. The works of the said Bessel, of Struve, of Argelander, and lately those of Auwers and Newcomb, set out by admitting that the modern era of precise astronomy opens with Bradley, as the era of the Renaissance began with Tycho Brahe, and the Hellenic with Hipparchus. Each of those three great observers had his precursors, whose work seems to establish a mysterious continuity with the astronomy of the civilisation immediately preceding it. Aristillus and Tymocharis, the first Alexandrian observers, are connected with the astronomy of the Oriental nations; King Alfonso of Castile, Paolo Toscanelli and Regiomontanus with that of the Arabians; Hevelius, Cassini, Flamsteed with that of the Renaissance. But as in the great catalogue of Hipparchus we have the measure of what the genius of the Greeks could give when applied to observations of the heavens, as only in the celestial places determined by Tycho Brahe we have the material for the new planetary theories of Kepler, which led to the discoveries of Newton, so to Bradley (and to Bradley alone) we must refer the rational application of these delicate means of astronomical observation that, revealing the most minute corrections to be applied to the places of stars, led to the foundation of a sidereal astronomy. The precession of the equinoxes more rigorously determined, the nutation of the terrestrial axis and the aberration of the fixed stars discovered and measured in their effects; the places of 3222 stars exactly settled in regard to the fundamental circles of the sphere, with a precision unknown till now, and comparable only to that of the modern meridian observations; these are the fruits of the long, fatiguing and sapient vigils of the Royal Astronomer in that Greenwich Observatory whence astronomy issued transformed one hundred and fifty years ago.

But if Bradley merited in the competent and severe judgment of Bessel the glorious epithet of *vir incomparabilis*, if Lindenau and Struve had been able to say that astronomy had been renovated at Greenwich and that the work of the great English observatory surpassed at the end of the eighteenth century all remaining astronomical productions, if, after the exhaustive discussion of Bessel (*Fundamenta Astronomiæ*), Bradley's work has still been good enough for a more refined elaboration in the last quarter of our century, by the merit of Auwers, who has given it all the value of which it was intrinsically susceptible, it is no longer allowable nowadays to put entirely on one side all the material that has been accumulated from 1750 till now, and which ought to concur with Bradley's observations in fixing with all possible approximation the values of the fundamental constants and the coordinates of the leading stars. As to what refers more especially to the precession of the equinoxes and to the proper motions of the stars, it is undeniable that the value of Bradley's observations is notably augmented by their antiquity: the greater the length of time that has elapsed, the more is manifested the influence of corrective terms, in which time itself is multiplied by the coefficient of the precession or by the proper motion on the one or the other coordinate. But to render such influence really efficacious in the calculation of the factors that enter into the same terms, it is necessary that the lapse of time should be so great as to carry the terms that contain it to a higher order of term (unknown) that represents the accidental and systematic errors of the places settled by Bradley. Now no one could affirm that the century and a half that has passed between Bradley and our time be sufficient for this; on the contrary, indications are not wanting that authorise an opposite opinion. Shall we, for this, resign ourselves to a perfectly passive indifference, allowing time to mature the terms still too restricted? For the accidental errors, there is nothing else to be done; but they are not the most dangerous, and, on the other hand, the abundance of Bradleyan observations would allow us in many cases to rely upon fortuitous compensations. For the systematic errors, however, the case is different We can and we ought, with all the means of investigation with which the improved state of the science furnishes us, to seek out those systematic errors that still remain in Bradley's Catalogue, even after the acute revision of Auwers. Such a work would in no wise be irreverent to the labours of the talented Berlin astronomer, who, for the first, has given us precious materials for investigations of that sort, by his new and masterly discussion of the observations that Tobias Mayer made at Göttingen, contemporaneously with those of Bradley. It is necessary in a special manner to ascertain (as my revered master Schiaparelli suggests to me) whether and how far it is possible to render independent of Bradley the enormous amount of observations made by Piazzi at Palermo between 1792 and 1814. To such research I am now attending, while at the New York Observatory (through Dr. Davis) and at Turin the elements are being prepared in accord for a new reduction of the Palermitan Catalogue. Until such a reduction be completed, and until analogous researches have been instituted on all the observations that can lend themselves to the solution of the problem, and that were executed in the first half of the century, it will be vain to impose by international agreement the values for the precession and for proper motions that should be not provisory. The antiquity of the equinoxes observed by Bradley is not sufficient title to make us exclude *à priori* equinoxes more recent but more precise, those observed in Germany especially. For the needs of astronomy until now Bradley's work has rendered incalculable service; but what Bradley could by himself give, he has given. It is perhaps illusory to believe that a deeper and minuter discussion (as is undoubtedly Newcomb's last, compared to those of the Struves) can lead us to a more intimate knowledge of the truth.

But it is not alone in the exclusion of intermediary observations, of those in a special manner belonging to the first half of our century, that the conclusions of the Paris Conference find serious objections, for what refers to the precession and to proper motions. As Prof. Lewis Boss notes in a deep and animated paper in the *Astronomical Journal*, two great astronomical undertakings adapted to throw new light on the controversy await their fulfilment: the zones of the *Astronomische Gesellschaft* and the Catalogue of the Paris Observatory. Notwithstanding the differential character of the first, and the heterogeneous origin of the second, Prof. Boss thinks that we cannot estimate from these two copious springs of information on the proper motions, in which the abundance of data compensates (in certain limits at least) their dependence upon the errors of the fundamental systems adopted.

Allow me to add another consideration to those put forward in all competence by the American astronomer. The problem of the precession is indivisible, as we have said, from the problem of the proper motions: the problem of proper motions may depend in its turn on the displacement of the solar system in space. Now there is no doubt that a solution, fit to be considered definitive for a long series of years, is still wanting as to the last problem. And the reason of it is clear: it has been till now attacked on different sides, but always with individual method, inherent (we must say) to the state of science, that has not yet mobilised all its forces for a simultaneous attack. The classical methods based on confronting between stellar coordinates observed at many years' distance, and on subtracting in the observed displacements the parallactic part from that due to the real motion of single stars, are singularly convenient to determine the directions of the translatory movement of the solar system. To determine its velocity it is instead more convenient to use spectroscopic methods, with which the velocity of each star is measured in the direction of the visual ray. The very brief time that has elapsed since the day that Vogel, at Potsdam, with such ability rendered possible the measurement on the photographs of the slender and nearly imperceptible displacements of the spectrum lines, has not yet allowed this method to be applied in all its potentiality, the fecundity of which Secchi had already divined, as many worthy observers, such as Pickering and Maunder, had attempted to practically employ it. When the new photographic equatorial (to be mounted at Potsdam) has given the means of studying a large number of stars inferior to the second magnitude (which is the limit till now of the instrument used by Vogel), when the rigorous proceedings of the illustrious German spectroscopist become familiar to the American astronomers, who until now are perhaps the only persons to whom the question of expense presents no difficulty, when a new installation is to be made, then, and only then, the moment for approaching the solution of the problem of the solar translation in space by the medium of a rational combination of astronomical and spectroscopical methods will be arrived.

Once the movement of our system is known with sufficient exactitude, it will be easy to eliminate its effect from the proper motions of the stars, which can then be reduced, free from all systematic part, to the merely accidental variations of the coordinates, and can therefore be treated as accidental errors, and submitted to calculation, together with the eventual correction of the constant of precession. This will only gain in precision the longer its deduction is delayed, which, for obvious reasons, may be afterwards made definitive for a long series of years. It is exactly for such a consideration that I think it right that all the equinoxes determined after Bradley's, and which are not affected (as those of Piazzi are) by incurable errors, should be used in the new determination of precession, it being possible only, from the comparison of these equinoxes, to rise again by extrapolation to Bradley's epoch, with data adapted to render clear the law of the systematic errors remaining in the revision of Auwers.

As to the nutation, it does not seem that the value 9″·21 of this constant, adopted by the Conference, has yet given rise—at all events, in public—to disputes and oppositions. Anyhow, it will not be useless to remember that fresh rigorous determinations of it were by several authorities demonstrated to be necessary in recent years, and that especially the persistent uncertainties have their being through the disagreement, not yet well explained, existing between the value of the terrestrial flattening given by the mechanical theory of the nutation and that given by geodetical measures. Harkness has sustained the need of a new series of observations, tending to furnish a new value of the constant of nutation, more precise than that of Peters. While such a series is projected and executed (and it will be necessary to prolong it at least for one of the periods of nineteen years that reconduct the node of the moon's orbit to the equinox), the discussion of the enormous geodetical material that is being accomplished will furnish us more secure facts as to the flattening and to the moments of inertia of the earth, thanks to the comparison between the values given by the arcs of meridian and by the measured lengths of the pendulum for seconds. Hence a correction (that can be but arbitrary) seems premature as to the value already assigned by Peters, whose exactitude, according to Harkness, is remarkable.

For the solar parallax, the Conference thought it opportune to fix a value of 8″·80, by an act of authority unjustified by sufficient explanations. This appears to many astronomers to be an acceptable mean among the most discordant values that laborious researches have furnished in the last twenty years. The lamented Tisserand found no other motive for being satisfied with this choice, except its approach at less than a hundredth part of a second to the value fixed by Laplace. But the example of the famous mistake of Encke, not too opportunely quoted by him, should have admonished him to use greater prudence. We have, it is true, two distinct groups of results in these last years; some approximate to the value of 8″·75, the others about 8″·85. Are we to conclude that the first defect 0″·5, the others exceeding as much? Or is it not—given the great intrinsic accordance of the single determinations on which every value reposes—more legitimate to suspect that some series are affected by constant errors relatively enormous, and such to take weight from them all in the definitive discussion? The fact is that, notwithstanding the transits of Venus and the oppositions of Mars, notwithstanding the photographs and the heliometers, or the combined forces of men of value like Gill, Auwers, and many others, the problem of the parallax remains more open than ever. It is true that, as Boss remarks, one active period for this research seems at an end; but it is true also that, on the contrary, the question of the aberration is more lively than ever; and that, in the present state of astronomy, it would be absurd to settle the value of the former just when the greatest efforts are concentrated on the latter. To avoid contradictions, I see nothing better at present than to adopt (which, for the immense majority of astronomers, would simply mean to preserve) the constant of aberration given by Nyren, and the corresponding parallax, as it is calculated with the last value of the velocity of light, determined by Michelson at Breteuil. In a few years the material for a new calculation of the aberration will not be wanting; each of the series instituted lately for the study of the variations of latitude at short periods will furnish a useful element for discussion.

We see from this rapid analysis how all fundamental problems of astronomy, even being connected with each other in a single problem, by effect of the equations of condition that unite the single constants, can, for simplicity of investigation, be gathered in diverse groups, according to the more intimate dependence of some constants upon others. We see also that the gigantic general combination, attempted by Harkness a few years ago, is really premature, but has notable importance, as the first essay of the method which sooner or later must be used. Harkness' work in every way teaches us the inutility, or at least the small efficacy, of isolated researches, that are not sought to be coordinated with the analogous researches on elements of the same group. If it be too bold to establish the solar parallax on several dozen physical constants, mechanical or astronomical, bound more or less with it, it would be too timid and behindhand not to take into account with it the velocity of light, the stellar and planetary aberration, and the variation of the geographical latitudes. The nutation joins with the constants that define the figure of the globe and the law of the distribution of matter in the internal strata of it. Finally, the precession is united to the proper motions of the stars, and to the translation of the solar system in space, elements which in their turn depend on the systematic corrections of the stellar catalogues.

A general renovation, then, of fundamental astronomy must precede a new and authoritative definition of the numbers that the twentieth century must accept as the more probable values of the constants. The compilation of a fundamental catalogue, which must be the consequence of all this work, cannot be subordinated to considerations of opportunity, and much less to what Dr. Chandler shrewdly calls the "sentimental association vulgarly attaching to round figures." If, for reasons foreign to science, the editors of the *Connaissance des Temps* and of the *Nautical Almanac* will not accept the Newcomb's or the Auwers' stars, let them keep their own; the slight residuary discrepancy between the ephemeridæ will certainly be less harmful than agreement on a new provisional system, that, not having more value than the existing ones, would acquire superior authority without justifiable motives. Dr. Auwers, who is undoubtedly the most competent person in such matters at the present time, has well delineated the limits of his fundamental catalogue, calling it not purely and simply fundamental, but "fundamental for the observations of the zones of the *Astronomische Gesellschaft*." In other words, he has not intended to do anything else than furnish an indispensable basis for the great international undertaking about the zones, and has set up a guard against extending the signification of "fundamental" that should legitimise every delicate use of his stellar positions. The researches to which he is attending now, and to which the Paris Conference justly attributes "un intérêt scientifique de premier ordre," prove how in his mind (as in those of all the astronomers assembled in Paris) the fundamental catalogue now in use may be considered alike provisional, just as the new catalogue to be compiled at the end of this century for the needs of national ephemerides. To give to-day the title and the authority of a fundamental catalogue to a collection of stars is not sufficient in fact for the single stars to answer simply to the conditions which are enumerated at page 6 (Appendix C) of the *Annuaire du Bureau des Longitudes* for 1897; it is necessary that their positions be founded on absolute observations, executed with all the precision of which perfected modern instruments are susceptible, and on an exhaustive discussion of the series obtained till now on the same stars at Greenwich, Pulkova, Leyden, Washington, and in a few other observatories. For the present time the needs of the practice will be satisfied with collections like those of Auwers, Boss, Safford, and similar astronomers.

After all, if an international accordance were proposed exclusively to cause the four great ephemerides to adopt a uniform system of constants and of fundamental stars (as it appears to have been decided at Paris), without taking care at the same time that the reasons for the preference granted to such a system should consist in the undeniable superiority of it with regard to every other pre-existing, one might say that the agreement shows the absurdity of losing time, labour and money in the compilation of four different ephemerides, whilst one alone is enough for the needs of astronomy and navigation. In fact, for what object are four separate bodies of calculators employed to draw from planetary tables the places of the sun, moon and other bodies of our system? Would not one office alone, even international, be more than enough, and one sole almanac, published in several languages? And would it not be convenient to profit by the occasion to separate more clearly than has hitherto been done what is necessary for astronomers from that which is sufficient for geodetical observers, for geographers, for sailors? The papers in the *Astronomical Journal* touch this matter with great ability, calling attention to the fact that the national ephemerides (except, perhaps, that of Berlin) show rather too much the effects of their practical destination; if this could be fused with the supreme scope of astronomy some centuries ago, when the decay of astrological tendencies obliged science, from reasons of self-preservation, to find for herself a utilitarian basis, it is not at the end of the nineteenth century that she should found on its applications the justification of her existence. Like geometry, like all positive and speculative knowledge, like fine art, even the science of the stars aims especially at the honour of the human mind, and, from this point of view, the discovery of Neptune is worth as much as the discovery of a new salutary remedy or of a new electrical engine. On the other hand, the positions of the stars and planets are now known and calculated with a precision far superior to that which suffice for the applications. An immediate accord like that of Paris seems thus superfluous for applied astronomy and premature for pure astronomy. In any way, I agree with Messrs. Boss and Chandler in the view that if an agreement is to be come to, it is not in the form in which it was given at Paris. American astronomers justly note that the bureaucratic governmental character of the four offices publishing the ephemerides is not a sufficient title for them to represent all official and private astronomical science of the different countries in the definition of a merely scientific controversy of such moment. The directors of the four ephemerides indisputably occupy an eminent position amongst their colleagues; but, whatever may be their personal merits, their opinion (in a matter that touches the foundations of science) is not such as to impress itself authoritatively and without discussion.

Moreover, I allow myself to add that such an opinion cannot bind that of the numerous astronomers that belong to countries where ephemerides are not published, and where they are compiled (as at Trieste and at San Fernando) second-hand. The resolution adopted by the organisers of the Conference of inviting Messrs. Gill and Backlund, with a deliberative vote, Messrs. Van de Sande Bakhuyzen and Trépied with a consultative vote, does not seem to me to represent anything more than a well-deserved homage rendered to those learned astronomers, and perhaps might contribute to render more significant the exclusion of other countries, such as Austria-Hungary, Italy, Sweden, Norway, Denmark, the Argentine Republic, whose astronomers till now have strongly and efficaciously contributed to the theoretical and practical study of the arguments. As to what refers specially to my own country, it may not be inopportune to recall to mind the ancient series of ephemerides published, first at Bologna, afterwards at Milan, which was interrupted twenty-five years ago in order not to lose time and money by repeating what was abundantly done at Paris, Berlin, London and Washington. The history of the Milan Observatory in this last quarter of the century, proves that the promises made by its director Schiaparelli were not vain, that thus the Observatory might "dedicate itself with greater alacrity to those researches that constitute the real progress of science" (*consacrarsicon maggiore alacrità a quelle ricerche, che costituiscono il vero progresso nelle scienze*).

Finally, I believe that the discussion on the conclusions and aims of the Paris Conference should be continued by correspondence in scientific periodicals, as well as by direct treaty between the more competent bodies. And, perhaps, it would not be without some utility were the Royal Astronomical Society and the *Astronomische Gesellschaft* to agree to examine and extend the plan devised some few years since by Dr. Gill for an international Congress of Astronomers, by which alone the deliberations of the Conference could have full and authoritative sanction.

FR. PORRO.

P.S.—The present paper was already finished when I read, in No. 413 of the *Astronomical Journal*, Prof. Newcomb's reply to the criticism of Prof. Boss. Notwithstanding the reasons strenuously advanced by the learned astronomer of Washington in support of his proposal of a new value for precession, it does not seem doubtful that the question must be considered from a wider and more general point of view. No one contests the delicacy and the rigour of the procedure adopted by Newcomb in drawing out his precession: no one denies but that he has treated the difficult argument in a masterly manner, enlightening it with his original and profound views. Where it seems to me that Boss dissents from Newcomb is in the opportunity of expending such talent and labour about a material already exhausted and not susceptible of giving more sure results, in whatever way it be treated. In any way, even accepting the Newcomb's new contribution to the study of the particular question of precession with the praise due to it, the general question still remains open.—FR. P.

The Treatment of Stamp Battery Slimes from Gold Ores.

ON page 501 of your issue of September 23, there is given a brief abstract of a paper read by myself at the July meeting of the Chemical and Metallurgical Society of South Africa.

The essential features of the paper have hardly been correctly rendered in the condensation, inasmuch as at present mechanical stirrers are employed for agitation of slime-pulp, jets of air serving merely for oxidation, though their use as a means of agitation is suggested.

The primary use of aeration is described in the paper as the oxidation of FeS, FeO_2, H_2, and other reducers, so as to effect a preliminary preparation of pulp before adding cyanide; hence the KCy is not protected by the presence of FeS, which, with other ferrous compounds, has already undergone oxidation and become converted to ferric hydrate, in which state it neither consumes cyanide nor abstracts oxygen.

The CO_2 in the air blown through the pulp is neutralised by the free alkali (CaO_2H_2) present, which thus serves to protect the KCy from decomposition.

W. A. CALDECOTT.

Johannesburg, November 8.

Abnormal Colours of Flowers.

WITH reference to your correspondent's communication in NATURE for December 2, on abnormal colours of flowers, I fancy the following note may be of interest. Towards the end of

August 1894, near the Bernina Hospice in Switzerland, I came across several plants of myosotis growing by a pool. In some cases the flowers were a bright blue, but in others they were distinctly pink, several being entirely pink, and others showing pink blotches and lines. The plants were in a hollow, and on the day of my visit there was an extremely cold wind blowing.

London, December 2. HECTOR COLWELL.

Fire-fly Light.

REFERRING to my reply to Prof. S. P. Thompson (NATURE, July 29), concerning fire-fly light, I can confirm what then I wrote. Mr. H. Muraoka has sent to me from Kioto in Japan a letter from which I derive the following particulars. (1) In the neighbourhood of Kioto there are about nine kinds of *Luciolæ*, which Mr. H. Muraoka continues improperly to call, in German, Johanniskäfern. (2) The insects used by him were probably *Luciola vitticollis* and *Luciola picticollis* (Kiesenw.).

Florence, December 1. CARLO DEL LUNGO.

AN ENGLISH BEAVER PARK.

SINCE the Marquis of Bute established a colony of beavers on his estate near Rothesay in 1874, no such interesting experiment has been made in acclimatising these animals as that which Sir Edmund Loder has carried out in Sussex. The beavers have now been inhabitants of his park at Leonardslee, near Horsham, for eight years, or rather they occupy an enclosure inside the park. There they have been placed on the banks of a small stream, with a rather rapid fall, a situation which exactly suits them. It is sheltered, for the valley is deep and wooded, and there was an ample supply of timber, large and small, in the enclosure when the industrious beavers, reversing the story of "Settlers in Canada," were brought from Canada and settled in Sussex. In the course of their eight years' sojourn they have ensured their comfort by constructing in great perfection, and in the most durable form, the engineering works for which beavers are so justly famed, and which gave rise to the Indian legend that the Creator, after separating land from water, employed gigantic beavers to "smooth" the earth into shape. Meantime the colony increases in number, so that some of the produce have been sold to go elsewhere. Nevertheless the beavers' industry is such that the size of their works, and consequently the area of the pool which they have formed, constantly increases.

The space in which they were originally enclosed was less than an acre. This was only one-third of the size of the Marquis of Bute's "beaver park"; but it gave quite sufficient scope for the beginnings of the colony. It was surrounded with a corrugated iron fence, which the beavers could not gnaw down, while at the same time they could not see through it, and so felt more secure and "private" in their park. Beaver engineering is directed entirely to one end. This is to form a pool deep enough and wide enough for them to be able to swim beneath the water to the entrance of their burrow, and to keep this entrance submerged in dry weather, when the streams run low, and covered with such a depth of water that even in the longest frosts, when the ice in Northern Canada is two feet thick, there shall still be water-space below it.

In the water the beaver knows it is safe; and, though it also stores branches for food below water, fastening them down with stones and mud, it is to serve as a place of refuge rather than as a storehouse, as a combined moat and temporary hiding-place, that the beaver forms his pool. All his clever engineering, his wood-cutting, building, canal-making and construction of "rolling ways," are subordinate to this end. The two last works, the beaver canal and the beaver road—the one for floating, and the other for rolling logs to the pool—are only brought into play when the supply of timber near at hand is exhausted. But they are part and parcel of beaver devices, and, though only recently brought to notice, are not less creditable than their other feats.

In the present paper we shall not use the technical phrases of hydraulic engineering, but term the reservoir made the "pool," and the containing barrier the "dam." In Canada, when the beavers were numerous, these dams were noticed to be so nicely adjusted in form to the material with which they were made, and to the force of the stream which they barred, that they could be classified in relation to these circumstances. Dams built mainly of mud and stones had a different section from dams built of sand and wood; and some made across rapid streams were curved, to resist the extra strain. But the greater number were made of battens of wood about three feet long, with the crevices stuffed with mud, stones, and the twigs and small branches; and in every case the first engineering principle necessary in the construction of a dam is observed. This is that the top shall be exactly level, so that the water of the pool, which must overflow, because the stream enters it from the top end, shall flow evenly over the whole length of the dam. As every one conversant with that most difficult form of the profession—river engineering—knows, any small gap or inequality soon ruins a dam. The water pours through these by preference, and at once cuts a gap. The beavers know this, too, and at Leonardslee, no less than in Canada, constantly examine the top of the dam, and mend the smallest gap along the line. The Leonardslee dam is of the ordinary kind, not curved but straight, and built of battens of wood, made of the boughs from trees cut down inside their enclosure, or from those which were given them as food. In all cases they ate most of the bark; then they cut the sticks into lengths of about three feet, and worked them into the structure. Plenty of mud was pushed into the crevices on the upper side, and all the small twigs and sticks were pushed in to make the whole dam tight. With great judgment they spared a small oak growing just below the dam. This now acts as a support to the structure; all the other trees in the enclosure, except those protected by metal guards, and one very large fir, were either felled, or attempted to be felled. It seems obvious that they kept this tree purposely as a buttress; for the dam is made higher and, therefore, wider each year, as the pool above increases; the tree is now almost in the centre, and its roots are already worked into the dam foundations. Even the baby beavers at Leonardslee, no bigger than rabbits, are put to "light jobs" in mending the dam, and the elders are most industrious. Each winter brings down a quantity of mud, which would make the pool shallower. But the beavers raise the dam so rapidly that the pool gains in depth, and spreads for a long distance up stream and laterally. The dam is at least five and a half feet high, and the depth of water above it five feet, yet it is so well made that, though the human-built dams of several artificial pools higher up the stream were carried away in a winter flood, the beaver-dam was undamaged. Near the point at which the stream enters the enclosure three large trees, formerly on the bank, are now submerged in three feet of water, owing to the fresh height added to the barrier below. The beavers had begun to cut these trees down—a very hard task, but one in which they would have succeeded had not the water risen so fast that they were floated off their legs when trying to go on cutting. One large beech tree, standing on a raised bank washed by the ever-increasing pool, was an object of envy to the beavers. They concluded that the quickest plan was not to cut it down, as it was very large and the wood hard, but to dig it up. So, with the aid of the increasing waters, they undermined the tree, which fell across their pool. This gave them occupation for some weeks. They ate every morsel of bark off the trunk and branches, and then cut off the boughs, gnawed them into lengths, and took them to the dam and to their "lodge." The latter began as a burrow in the bank. As they gradually enlarged this, and filled up the bottom with wood chips, they broke open the roof to get head room, and constantly added to the dome with mud and sticks. It is now a large untidy mound on the bank, which at this point is steep.

The process described above accounts partly for the evolution of the beaver lodge from the burrow. But the keeper of Lord Bute's beavers stated that the beavers at Rothesay did clean out the old shavings which they took in to make beds of, and plastered them on the outside of their lodge, or on the same embankment. The present writer inclines to believe that this is likely to be correct, not in every case, but in some, for it is very much in keeping with beaver character. In such cases he ventures to offer the following solution of the growth of the lodge, in cases where the beavers remove their bedding of chips. The water above the dam, owing to the causes mentioned above, rises higher yearly. This must also raise the level in the sub-aqueous passage leading to the beavers' chamber, and in time tend to invade the chamber itself. To remedy this the beavers would naturally raise the floor, and leave the débris of old "beds" on it, piling fresh stuff on the top, and at the same time quarry out the roof, both for head-room and to get fresh earth for their floor. When once the artificial roof was made the same process would go on, until the rising water flooded out the floor altogether, and surrounded the lodge, as one sees it in old Canadian pictures. The lodge would thus take the beehive, moated, form which it has in those conventional plates, even though it lacks the windows which the French artists added for effect. The beavers occasionally escape by burrowing under the corrugated iron fence. This is not always intentional on their part, and they are easily caught again. Whenever one gets out it travels up the stream, visiting the pools above. There a box-trap is set next night, baited with dog-biscuit, of which the beavers are fond, and the animal is certain to be caught. One beaver, out for a stroll like this, tried to cut down a large Scotch fir, and did cut down a silver birch. The first indication to the keeper next morning that a beaver had escaped was the sight of this tree, in full leaf, lying across a path.

We mentioned above that the Leonardslee beavers had not made either a canal or a rolling path. There is no need for either; for there are no more trees to cut down, or logs to roll from a distance. But it is worth devoting a few lines to these, two of the less known, but not least extraordinary exhibitions of beaver intelligence. An old-established colony soon clears off all the timber near its home. In order to convey the more distant logs to the dam they carefully clear paths, and roll the battens of wood down to the water. But the beaver canal, to which proper attention was first drawn by Mr. Lewis Morgan, is, in the writer's opinion, more wonderful still. It is nothing more nor less than a waterway, or several waterways cut from points on the stream to such parts of the adjacent plantations or woods as the beavers wish to visit, or cut timber in. Sometimes, also, it is made through the centre of an island, to make short communication by water. To this canal the beavers roll their logs, and then tow them to their dam. It has been urged that these canals are accidental, merely worn out along the customary roads; some are, no doubt. But wherever the writer has seen tame beavers kept, even at the London Zoo, he has seen them at different times cut trenches to the edge of their pool, though as that at the Zoo was surrounded by a stone rim, the beavers could not fill the trench with water. Of course, there this trench was only a few feet long. But it is quite clear that Lord Bute's beavers, which had a considerable area in which to cut their timber, tried to dig canals. This is the description given by their keeper, who, though well acquainted with beaver stories, evidently had never heard of the canal. "Their burrows they make by cutting a road from the middle of the dam for several yards into the dry ground, where they scoop out a dome-shaped burrow. . . . Some of the roads to these burrows are from fifteen to twenty yards long, *and so level that the water follows them in the whole length*"! Here is, undoubtedly, an instance of the beaver canal.

Those who care to compare the methods of the Canadian beavers acclimatised at Leonardslee with the works and ways of the European beavers still surviving in Norway, will find an interesting account of the past and present history of the Norwegian beaver, by Mr. R. Collett ("Bæveren i Norge"),[1] illustrated with twelve plates of beaver lodges and dams, and supplemented by an English summary.

The beavers' present range is confined to the Stifts of Christiania and Christiansand, but a few remain on Bratsberg Amt and Stavanger Amt. The larger colony is on the River Nisser (or Nid), the westernmost colonies being on the river Mandal. In all cases they feed not on fir, but on deciduous trees, mainly the aspen. When not on the banks of large rivers they make dams, one of which, near Hellersli (Trungen), was built entirely in three weeks, and formed a lakelet more than 100 yards across. The length of the dam was 14 metres. In only one respect do the habits of the Norway beavers differ from those of the Canadian species. Those that live on the banks of the large rivers cannot make a dam over such rapid and deep waters. Yet these rivers rise and fall, and there is a danger of the lodge being either flooded or left high and dry. In these places the beavers build long lodges, at right angles to the stream, and sloping up the bank. When the river rises, the beaver can go up to the higher end of his lodge; when it falls, the entrance is still submerged and safe.

In 1880 Mr. Cocks estimated the number of beavers surviving in Norway at 60; in 1883 Mr. Collett believes there were 100. Since 1894 and 1895 the beavers have been protected by law in their two principal haunts, for a period of ten years in each district.

C. J. Cornish.

SCIENTIFIC INVESTIGATIONS OF THE LOCAL GOVERNMENT BOARD.[2]

The Annual Reports of the Medical Officer of the Local Government Board constitute in many respects the best treatise on practical hygiene we possess. Their diligent perusal by the embryo health officer would equip him as no ordinary text-book can do for the intelligent discharge of his duties. It would be well if candidates for Public Health degrees were examined upon the salient features of these reports. The volume for 1895–96, which has just been issued, contains certain features of interest. There is the usual admirable summary of the year's work by Sir Richard Thorne; statistics with regard to vaccination, and a compilation of returns of notified infectious diseases in urban districts and in the county of London. Valuable reports are also contributed by Dr. Copeman and Dr. Buchanan upon outbreaks of enteric fever, and by Dr. Sweeting upon an outbreak of diphtheria. The able report by the late Mr. R. W. Thomson upon the sewerage and drainage arrangements of certain valleys in the counties of Monmouth and Glamorgan, leads one to join in the regret expressed at the loss of this talented official. It is, however, the auxiliary scientific investigations which call for more special notice in these columns.

---

[1] Bergen: Grieg's "Bogtrykkeri."

[2] Twenty-fifth Annual Report of the Medical Officer of the Local Government Board, 1895-96.

The several cases of Asiatic cholera that occurred in this country during 1893, led the Local Government Board to keep a diligent watch in the subsequent year over any cases that presented symptoms of a choleraic nature, and Dr. Klein gives an account of the bacteriological examination made by him in twenty-nine instances. The comma bacillus was not found in any of the cases; they therefore proved to be examples of cholera nostras, or English cholera. This conclusion is a further confirmation, if that were needed, of the diagnostic value of Koch's methods. When Dr. Klein says, "if the vibrio of Koch could be demonstrated in the bodies of persons not connected in any way with the cholera localities of 1893, the bacteriological test as an important help in distinguishing between Asiatic cholera and cholera nostras would become practically worthless," he is surely suggesting a doubt that does not exist amongst the great mass of observers. In a number of the cases the bacillus coli was found to be the predominant micro-organism. Of fresher interest is Dr. Klein's description of an organism isolated from cases of diarrhœal illness due to the consumption of milk, and named by him, "Bacillus enteritidis sporogenes." There is a misleading sentence on p. 196: "ordinary milk, such as is bought in many a shop in London, contains as a rule an abundance of bacillus coli, and if put aside it will rapidly 'sour' and coagulate spontaneously owing to the multiplication of bacillus coli." This might lead most readers to assume that the ordinary "souring" of milk is due to bacillus coli, and not, as is the case, to one or other of a considerable number of lactic acid producing organisms. Dr. Klein proceeds to a further report on prophylaxis in diphtheria, in which are mainly detailed the results of injecting living diphtheria cultures into the horse with the view of obtaining antimicrobic substances in the blood. The experiments do not appear to have brought out results of practical value, either with his own "antimicrobic" serum, or with antitoxic serums obtained from various sources. Dr. Klein also contributes a "Further Report upon Protective Inoculations" which will be read by all interested in the subject of which it treats.

"Snake venom in its prophylactic relations with 'poison' of the same and of other sorts," is the subject of a lengthy communication by Dr. Kanthack. The work of Calmette and others upon the effect of cobra antitoxic serum upon the poison of snakes other than the cobra is discussed, and there follow observations upon the nature of the immunity of certain snakes to certain snake poisons. Dr. Kanthack has not been able to confirm Calmette's statement, that the injection of solutions of chlorinated lime have value as a curative or immunising agent. On the other hand, as Calmette states, an antitoxic serum can be produced in rabbits by administration of the cobra poison itself, and still better results are obtained by using the mixture of venom and chlorinated calcium. The inhibitory influence of different antitoxic serums upon cobra venom is next dealt with. The experimental data given are in many respects incomplete, and it would perhaps have been well to wait till the experiments were finished before publishing any conclusions from them.

Dr. Kanthack instances the marked retarding influence of liver extracts on the action of cobra venom. This most interesting statement is supported by three experiments, and their continuation left for a future date. There follow notes on "immunising serum." It is again disappointing to find experiments quoted with the addendum, "the number of my observations are too limited." Attention should be drawn to an experiment Dr. Kanthack performed on himself with most remarkable results. In the course of nine days Dr. Kanthack swallowed 51·4 cc. of living and dead broth cultures of the cholera vibrio, and a solution of sodic carbonate to neutralise the gastric acidity. A week later blood was obtained from the arm, and 3 cc. of the separated blood serum was injected into each of three guinea-pigs intraperitoneally. Four days later the guinea-pigs were respectively inoculated with *B. prodigiosus*, *B. pyocyaneus* and *V. choleræ—only* the guinea-pig inoculated with cholera remained alive. The immunisation Dr. Kanthack had effected on himself *per os*, was apparently transmitted by means of his blood serum to the guinea-pig.

The paper concludes with notes upon Pfeiffer's, Bordet's, and Durham's tests for the cholera and typhoid organisms. It would have rendered the description clearer in one or two instances if it had been explained what actually was seen, instead of expressing the results as "not quite negative" and "did not react absolutely negatively." Dr. Kanthack considers that "a general conclusion at this stage as to the specificity of antitoxic or immunising serum would be premature," though the facts so far obtained tend to support this conclusion. The paper is one more adapted for perusal by specialists intimately acquainted with the subject than by the general reader, who might be apt to carry away false notions as to the finality of a number of the results obtained. One cannot resist the impression that the material for half a dozen researches has been crowded into the space of one paper.

The difficult subject of food poisons is considered from the bacteriological aspect by Dr. Cautley. The object of the inquiry was to ascertain whether the multiplication or pathogenic properties of bacteria normally present in the digestive tract, viz. *B. coli* and *Proteus vulgaris*, are influenced by association with the non-pathogenic organisms to be commonly met with in food. Dr. Cautley was able to demonstrate that the virulence of the above bacilli is increased by simultaneous injection with certain food organisms into animals. On the other hand, feeding experiments on similar lines gave negative results. Dr. Monckton Copeman and Dr. Blaxall contribute reports on the advantages of glycerinated vaccine lymph. The volume, like its predecessors, contains much of interest and value to sanitarians and bacteriologists.

THE ARCTIC WORK OF MR. R. E. PEARY.

ON Monday evening Mr. R. E. Peary, U.S.N., presented to the Royal Geographical Society a statement of the results of his Arctic explorations and of his plans for continuing these.

Mr. Peary has been engaged in exploring Northern Greenland for the greater part of the last ten years, and in the course of his sledge journeys he has had more opportunities of studying the inland ice than has fallen to the lot of any other explorer. The most remarkable journey of the series was that of 1892, when he crossed the ice-cap from Inglefield Gulf and discovered Independence Bay on the north-east coast of Greenland. This journey showed that the inland ice terminated to the north, and that there was no road that way to the pole. Land was seen to the northward, which Mr. Peary believes to be separated by a channel from Greenland, and to extend probably some distance beyond the furthest north attained by Lockwood on Greely's expedition, 83° 24′. A second journey to Independence Bay in 1893 was frustrated by the unexampled severity of the weather; the party, which started with forty-two dogs returned with only one. In 1895 another attempt was more successful, but the resources of the expedition and the transport available were insufficient to allow any advance beyond the position of 1892.

After this journey Mr. Peary resolved to wait until the results of the Nansen and the Jackson-Harmsworth expeditions were available as a guide to further work, but he had no intention of abandoning his endeavour to attain a high latitude on the American side. This summer he visited Cape York in a whaler, and succeeded in taking on board and transporting safely to New York a vast mass of nickel-iron weighing about 100 tons. This block is reputed by the Eskimo to have fallen from heaven, and it bears all the external appearance of a meteorite, while it shows the characteristic Widmannstätten figures when the surface of the polished metal is etched with nitric acid. The transport of the block was a brilliant engineering feat, as the only means available for getting it brought on board and lowered into the hold were hydraulic jacks and timber stagings. We understand that the great meteorite is still the property of Mr. Peary, and has not yet been acquired by any museum. It is not to be confounded with the masses of telluric iron described by Baron Nordenskiöld.

Mr. Peary's description of the inland ice was extremely graphic, and illustrated by a superb series of coloured slides, prepared from photographs selected from his collection of over 4000. The movement of the surface he believes to be due as much to the drift of snow by the wind as to the discharge of glaciers, summer melting and evaporation taken together. The snow-dunes in parts convert the inland ice into a veritable Arctic Sahara. In addition to collections of the restricted but brilliant flora of the ribbon of land freed from snow in summer along the coast of Greenland, much valuable scientific work was done. Ethnology is the branch of science which has perhaps been most advanced. The Northern Eskimo, the Arctic Highlanders of Sir John Ross, have been most thoroughly studied and photographed. The entire tribe numbers some 250 individuals, every one of whom is personally known to Mr. Peary. They have lived quite untouched by civilisation, and free even from communication with the Southern Eskimo. They are of good physique and, while far from attractive in appearance or customs, they possess many good qualities.

Mr. Peary, as the result of his experience of these people and of the conditions of Arctic travel, has formulated a scheme of progressive exploration which he will put into practice next year. Equipped by funds that are already provided, he proposes to take a ship up to Sherard Osborn Fjord in latitude 82°, taking two other white men and a picked group of eight or ten Eskimo with all their belongings. They will send the ship back and form a camp, advance by the autumn moonlight along the coast, and winter as far north as possible. In the following year the northward march would be resumed until the furthest point of land was reached. This he hopes to find in 85°, if not even further north. From the camp at that point as a base a rapid journey must be attempted over the sea ice to the pole and back, leaving most of the Eskimo behind. If the first year did not afford an opportunity the next year might, or at least the third. Mr. Peary's principle is to wait for favourable conditions, and he is prepared to remain at his most northerly camp five years if necessary. In the course of that time he believes that a door to the pole will open, or can be pushed open. This principle has always been approved by the leading Arctic men, and recent experience has amply confirmed the importance of not struggling against obstacles when it is possible, by skill or patience, to take advantage of natural aids.

Mr. Peary's project has in it nothing sensational; he holds no prospect of startling discovery before the public; and the fact that his expedition is already provided for, obviates any necessity for making an appeal for financial support. The enthusiastic character of his reception by a large and deeply interested audience can only be paralleled in recent years by the greeting accorded to Dr. Nansen.

NOTES.

It has been decided that the statue of Lavoisier, for which international contributions have been subscribed, shall be erected on the Place de la Madeleine, Paris. The Municipal Council of Paris have sanctioned this site.

M. Ditte, professor of chemistry at the Sorbonne, has been elected a member of the Section of Chemistry of the Paris Academy of Sciences, in succession to the late M. Schützenberger.

Prof. F. R. Japp, F.R.S., will deliver the Kékulé Memorial Lecture at the Chemical Society next Wednesday evening, December 15.

At the next meeting of the Royal Photographic Society on Tuesday, December 14, Prof. Gabriel Lippmann will read a paper on "Colour Photography." The meeting will not be held in the usual rooms at Hanover Square, arrangements having been made for it to take place in the theatre of the Society of Arts; a large gathering is anticipated. Non-members of the Royal Photographic Society will require admission tickets, which can be obtained on application to the Secretary at 12 Hanover Square.

We regret to see the announcement that Prof. Winnecke, the distinguished astronomer, died on Friday last at Bonn.

Lord Strathcona and Mount Royal, High Commissioner for Canada, will preside at Prof. Roberts-Austen's lecture on "Canada's Metals," at the Imperial Institute next Monday evening (December 13). The lecture, which will be fully illustrated by experiments, is open to the public, without tickets.

It has been resolved to hold an international fisheries exhibition in Aberdeen in the summer of 1899.

A skeleton of the moa was sold at Mr. J. C. Stevens' auction rooms on Tuesday, the price reached being forty-eight guineas. The bird was set up by Captain F. W. Hutton, F.R.S., from bones obtained at Enfield, New Zealand. The deposits in which these *Dinornis* remains were found was described by Dr. H. O. Forbes in Nature of March 3, 1892 (vol. xlv. p. 416).

A general meeting of the Aeronautical Society of Great Britain will be held on Thursday, December 16, at 8 p.m., at the Society of Arts, John Street, Adelphi, W.C. Major-General Sir Charles Warren, G.C.M.G., K.C.B., will occupy the chair. The following gentlemen and others have kindly arranged to exhibit apparatus:—Mr. Pilcher, a soaring machine and an oil engine; Major Moore, a model flying machine; Mr. E. S. Bruce, balloon signalling apparatus; Captain Baden-Powell, kites and a gliding machine; the Society, cinematograph of flying birds.

When a large number of crickets are chirping at night in a field, they do so synchronously, keeping time as if led by the wand of a conductor. Prof. A. E. Dolbear says, in the *American Naturalist*, that the rate of chirp seems to be entirely determined by the temperature, and this to such a degree that the temperature can be estimated when the number of chirps per minute is known. At a temperature of 60° F. the rate was found to be 80 per minute, and at 70° F. it was 120 a minute; this gives a change of four chirps per minute for each change of one degree.

The following are among the lecture arrangements at the Royal Institution before Easter:—Prof. Oliver Lodge, six Christmas lectures (specially adapted for young people) on the principles of the electric telegraph; Prof. E. Ray Lankester, eleven lectures on the simplest living things; Prof. Dewar, three lectures on the halogen group of elements; Prof. J. A. Fleming, five lectures on recent researches in magnetism and diamagnetism; Prof.

Patrick Geddes, three lectures on Cyprus. The Friday evening meetings will begin on January 21, when a discourse will be given by the Right Hon. Sir John Lubbock, Bart., M.P., on buds and stipules. Succeeding discourses will probably be given by Prof. C. Lloyd Morgan, Mr. A. A. Campbell Swinton, Dr. J. Hall Gladstone, Prof. L. C. Miall, Captain Abney, Prof. T. E. Thorpe, Mr. James Mansergh, the Dean of Canterbury, Prof. Dewar, and others. Lord Rayleigh will deliver lectures after Easter.

AT the meeting of the General Medical Council last week, the Committee entrusted with the duty of preparing the new edition of the British Pharmacopœia, submitted copies of their draft of the work for the approval of the Council. The estimated amount to be expended on its production will be about 6000*l*. The Committee suggest that the price of the volume might suitably be seven shillings and sixpence, but the power of actually fixing the price rests with the Commissioners of the Treasury. In order that the Pharmacopœia might be issued early next year, the Committee recommended that it be delegated to the Executive Committee to adopt the fully corrected work as The British Pharmacopœia, 1898, to communicate with the Commissioners of the Treasury on the question of price, to publish the Pharmacopœia, and to make the usual legal announcement of publication. The report of the Committee was adopted.

THE difficulties in the way of a permanent establishment of the Essex Field Club's County Museum of Natural History have been very largely removed by Mr. Passmore Edwards' munificent offer to build a museum at West Ham (adjoining the new Technical Institute) to contain the Club's collections, on condition that the building is maintained by the Corporation of West Ham as a permanent institution, and that it is opened on Sundays. The Town Council have gratefully accepted Mr. Passmore Edwards' offer, and arrangements are being entered into whereby the annual upkeep of the museum will be provided for by a joint fund subscribed by the Corporation and the Club. The task of gathering the collections, and the scientific control of the same, will remain with the Club. The museum is intended to illustrate the county of Essex generally, while the Club's smaller museum in Queen Elizabeth's Lodge, Chingford, will be confined to objects from Epping Forest—the two institutions being mutually dependent and illustrative, the one of the other. Further details will be issued when the negotiations are completed.

AT the last meeting of the Council of the Australasian Association for the Advancement of Science, the following gentlemen were proposed as vice-presidents of Sections:—Section A (astronomy, mathematics, and physics), Prof. A. M'Aulay and Prof. T. R. Lyle; Section B (chemistry), Mr. R. T. Bellemey, Prof. E. H. Rennie, and Prof. Orme Masson; Section C (geology and mineralogy), Mr. W. Howchin and Mr. R. L. Jack; Section D (biology), Prof. J. T. Wilson, Prof. C. J. Martin, and Mr. J. J. Fletcher; Section E (geography), Mr. P. G. King and Mr. A. C. Macdonald; Section F (ethnology and anthropology), Prof. W. Baldwin Spencer, Mr. Thos. Worsnop, and the Rev. Lorimer Fison; Section G (economic science and agriculture), Dr. H. N. MacLaurin, Mr. R. Teece, Mr. W. M'Millan, Mr. Sydney Smith, Mr. E. M. Shelton, and Mr. W. Farrer; Section H (engineering and architecture), Mr. H. Deane and Prof. W. H. Warren; Section I (sanitary science and hygiene), Dr. D. Hardie, Dr. J. W. Springthorpe, and Dr. J. Ashburton Thompson; Section J (mental science and education), Dr. A. Garran, Dr. R. N. Morris, and Mr. R. H. Roe. A large number of additional papers were announced as having been promised to the various Sections.

THE Meteorological Council have published a very useful volume of Rainfall Tables for the years 1866–90, based upon observations at 492 stations, selected so as to show as nearly as possible the general distribution of rain over the United Kingdom. The present volume has been prepared in connection with the previous set of tables for 1866–80 published in the year 1883, and while it includes in the general averages the monthly and annual means of the earlier series, it contains the separate monthly and yearly values for each of the years 1881–90, and of any years prior to 1881 which were not previously published. To facilitate the use of the tables, references to them are arranged both under counties and stations. There is no discussion of the observations, but the averages for the years 1881–90 are shown upon three maps, together with the main watersheds and the catchment basins of the principal rivers, and these exhibit the general distribution of the rainfall very clearly. The whole work has undergone careful supervision, and will be very valuable as a standard of reference in this branch of meteorological statistics.

THE meteorological observations made at the Rousdon Observatory, Lyme Regis, during last year, have been brought together by Mr. Cuthbert E. Peek, and published in the form of a Report. The observatory is a second order station of the Royal Meteorological Society. Mr. Peek not only describes the meteorological conditions and statistics of the different months of the year, but also records the results of a number of experiments to compare rain-gauges and anemometers of different kinds. A daily comparison of the actual weather experienced at the observatory with the forecasts of the Meteorological Office showed that, taking wind and weather together, eighty-eight per cent. of the forecasts were correct. Of wind alone, ninety-one per cent. of the forecasts were fulfilled; and of weather, ninety-two per cent. The most trustworthy forecasts were in August, there being only one day doubtful during that month. The lowest percentage of trustworthy forecasts was in January, as might be expected from the remarkable barometric movements of that month. A comparison of forecasts and actual wind and weather for the thirteen years 1884–96, shows that the percentage of successes was only fifty-nine in 1884, but in the following years it reached seventy per cent., and has been increasing year by year ever since. The best forecasts seem to have been made in 1894 and 1895, in which years eighty-nine per cent. of the predictions were fulfilled.

DR. VAN DER STOK, the Director of the meteorological and magnetical observatory of Batavia, has published a very comprehensive atlas, containing a large amount of information on the winds, weather, currents, &c., of the East Indian Archipelago. Some idea of the magnitude of the work may be formed from the fact that it extends to more than two hundred large folio pages of tables and charts, and that it embraces the whole area between the western coast of Sumatra and the northern coast of New Guinea. For forty different points of this area the meteorological conditions have been deduced for each month and for seasons, while monthly wind-roses have been drawn for the day and night separately. The work is divided into three parts: (1) observations made on ships; (2) rainfall and wind observations made on land; and (3) data relating to tides. The materials made use of in the first part have been extracted from many hundreds of log-books kept on Dutch men-of-war during the years 1814–1890, and were obtained from the Ministry of Marine at the Hague for the purpose of this discussion. The work is a valuable contribution to both the physical geography and meteorology of that portion of the globe, and will be of great practical use to navigators.

The first occasion upon which Röntgen rays were applied to surgical diagnosis was referred to by General Maurice in the course of a few remarks made at the close of a lecture delivered at the Royal Artillery Institution, Woolwich, by Mr. W. Webster. The credit of having first used the rays to determine whether a patient (who had severely injured his elbow) was suffering from a fracture or a dislocation, has hitherto been given to Mr. Howard Marsh. It appears, however, that Mr. Marsh really only recommended the application of the rays to the case, and that the actual photograph was taken by Mr. Webster, who had been working for some time with Mr. T. Moore. The photograph showed distinctly that the injury was due to a dislocation, and was not a fracture at all. The diagnosis having been established, the operation of putting the arm in its place was performed by Captain Salvage, an army surgeon. Mr. Howard Marsh described the case in the *British Medical Journal*; but, says General Maurice, "as he was simply dealing with it as a scientific case, the names of Mr. Webster and Mr. Moore were, according to professional etiquette, necessarily omitted." The lecture from which we gather these facts appears in the *Proceedings* of the Royal Artillery Institution (No. 5, vol. xxiv., 1897).

The Annual Report for 1896 of the State Board of Health of Massachusetts has just been issued. The work of the now historic series of experimental filters has been recorded as usual, and there is but little to add to the deductions already published in previous years regarding their respective efficiency in the purification of water. The presence of iron in public water supplies has been engaging the attention of the Board, and experiments have been started which, as far as they have gone, indicate that this evil may be remedied by filtering water through a fine filter of coke breeze, which is stated to practically remove all the iron. Another important matter which has been investigated is the purification of manufacturing refuse; such factory-sewage may contain several times as much organic matter as an equal volume of domestic sewage, and is extremely difficult to deal with; in many cases the chemicals used in manufacturing processes being such as would destroy nitrification if the sewage were applied to an ordinary sewage filter. The dissemination of typhoid fever through the use of polluted water in ponds in the vicinity of so-called "picnic groves"—places of summer resort brought within easy reach of large cities by the extension of electric railways—has also been carefully inquired into, and the sanitary conditions of a large number of such resorts and their water-supplies have been investigated. Other matters dealt with in the Annual Report are the production and use of diphtheria antitoxin; an experimental inquiry as to the diagnosis, genesis and diffusion of malaria; examinations of sputum and other material suspected of containing tubercle bacilli, &c.

At the meeting of the Chemical and Metallurgical Society of South Africa, held on October 16 last, some interesting data on dry crushing and direct cyaniding of Rand ore were given by Mr. Franklin White. Great things were expected of this method of treatment by some metallurgists a year or two ago, but its progress has been far from rapid, largely owing, no doubt, to the comparatively low percentage of gold extracted by its use. According to Mr. White, however, 917 tons of oxidised ore from Botha's Reef, treated recently, yielded 65·77 per cent. of its gold, the tailings containing 2·708 dwts. per ton. The only preparation of the ore was to pass it through a Gates crusher, after which nearly 20 per cent. remained on ⅛-mesh screens. Experiments seem to show that if the material had been passed through ⅛-mesh screens, about 76 per cent. of the gold would have been extracted in one operation. About 1000 tons of pyritic ore from the Village Main Reef were also experimentally treated with excellent results; one charge giving a theoretical extraction of 89·25 per cent., as deduced from the difference in the assays before and after treatment. The cheapness and simplicity of the process is much in its favour. In another paper read at the same meeting, Mr. Wilkinson estimated the present total costs of twenty-nine Rand outcrop mining companies as averaging only about 26*s*. per ton for mining, milling, development, &c., or about 4*s*. per ton less than in 1896, when the native wages were higher. A further reduction in cost of 4*s*. or 5*s*. per ton would be accompanied by an enormous increase in the profits. The life of the gold field is estimated at fifty years, and its average yield during that period at about 18,000,000*l*. per annum.

It is stated in *Engineering* that a company of considerable importance and with an influential board has just been formed in Sweden for the purpose, principally, of exploiting, through electric transmission, the vast unused power of the famous Trollhättan waterfalls, situated at some distance from Gothenburg, Sweden. The new company is to take over Dr. de Laval's waterfalls and property at Trollhättan, a carbide manufactory at Okan, with turbines and other installations, the Edenäs waterfall in Upper Lulea, and certain of De Laval's patents and inventions. There are in both places considerable areas of land, while the water-power at Trollhättan is estimated at 220,000 horse-power, and that at Edenäs at 100,000 horse-power. There is consequently both power and space enough for industrial installations on a large scale. It is intended to build a tunnel at Trollhättan, which is to receive the water above the falls in question (for there are others above it, already partly utilised) just above the "King Oscar Bridge," through which the tunnel will lead to a power station below the "Hell Fall." It is proposed to take some 20,000 to 30,000 electric horse-power through this tunnel. Of this power the company proposes as soon as possible to make available 10,000 horse-power, of which half has already been let to a well-known electrical engineer for a period of fifteen years. Of the 3000 horse-power (effective) at Okan, a portion is already being used for the manufacture of carbides.

A survey of the conditions of artificial flight, and the experiments which have been made in connection with it, is contributed to the current number of *Science Progress* by Prof. G. H. Bryan, F.R.S. It is pointed out that every one of the conditions for successful flight has been fairly satisfactorily dealt with by various experimenters; and it only remains to embody them all in a single machine. The directions in which the solution of the problem should be sought are thus summarised by Prof. Bryan:—"If any experimenter can so thoroughly master the control of a machine sailing down-hill under gravity as to increase the size of the machine and make it large enough to carry a light motor, and if, further, this motor can be made of sufficient horse-power, combined with lightness, to convert a downward into a horizontal or upward motion, the problem of flight will be solved. The first flights need not be long—a hundred yards, rising, say, twenty or thirty feet above the ground, will be sufficient; all else will be simply a matter of improving on the original model, and once success is assured workers will not be wanting. Another promising direction for success lies in an elaborate and exhaustive investigation of balance and stability, such as would allow of the safe use of motor-driven machines too large to be controlled by mere athletic agility. This might partially be acquired by experiments with models, gradually increasing in size till they were capable of carrying a man and a motor. But if the future development of artificial flight is not to continue a repetition of the chapter of accidents by which naval architects gained their theoretical knowledge, there is abundant work for mathematicians in reducing the conditions of stability of aerial machines to a matter of pure calculation. One thing is certain, till this is done designs of large air-ships for the wholesale transport of passengers, officers and cargo are not of the slightest value; their designers would do better to study mathematics, and help in the heavy work of calculation still requiring to be done."

For the purpose of testing whether change of chemical structure ever results in change of weight, Landolt carried out a number of experiments in the years 1890–92. Using a variety of reactions, he made a careful series of weighings, both before and after chemical combination, of substances sealed in glass tubes, but the results were inconclusive. In three reactions with silver sulphate and ferrous sulphate, producing silver and ferric sulphate, the apparent loss of weight was, on the average, more than nine times as great as the probable error of weighing, and a similar apparent loss was indicated as the result of six reactions between iodic acid and hydriodic acid. In some other reactions, however, the observed change of weight was sometimes positive and sometimes negative. A similar set of weighings for another silver reaction closely related to the one used by Landolt have now been made by Fernando Sanford and Lilian E. Ray, and are described in the *Physical Review* (October). The reaction used was the reduction of silver from an ammonia solution of the oxide, by means of grape sugar. The weighings show greater irregularities than those of Landolt, but they are still accurate enough to justify the authors' conclusion that the reaction used by them was unaccompanied by any such change of weight as was observed in the similar reaction studied by Landolt.

The September number of *Terrestrial Magnetism*, the publication of which has been unavoidably delayed, contains, among other contributions, a paper "Ueber die Fehler bei Erdmagnetischen Messungen," by H. Wild, and a translation of Prof. Max Eschenhagen's paper "On Minute, Rapid, Periodic Changes of the Earth's Magnetism," already noted in Nature.

A copy of an inaugural address on "Advances in Biological Science during the Victorian Era," recently delivered by Mr. Isaac C. Thompson as president of the Liverpool Biological Society, has been sent to us. The address is an instructive review of the most prominent biological work of the past sixty years, and the nature of it shows that the Liverpool Biological Society ranks high among the scientific bodies of the city.

Mr. Alfred Harker's excellent little guide to the study of rocks in thin slices under the microscope, published under the title "Petrology for Students" by the Cambridge University Press, has reached a second edition. The book has been revised throughout, and more attention has been given to American examples, at least among the igneous rocks. No better introduction to the study of petrology could be desired than is afforded by Mr. Harker's volume.

The Essex Field Club will publish about Christmas, as one of their "Special Memoirs," a volume on the "Mammals, Reptiles and Fishes of Essex," by Dr. Henry Laver, one of the Vice-Presidents of the Society. Taken in conjunction with Christy's "Birds of Essex," issued by the Club in 1891, it will afford a complete guide to the vertebrate fauna of the county. The work will be illustrated by original drawings by Major Bale, of Colchester, and Mr. H. A. Cole, of Buckhurst Hill, depicting some of the more interesting species and their haunts in the county.

The magnetic observations made at 509 places in Asia and Europe during the period 1867–1894, by Dr. H. Fritsche, Emeritus Director of the Russian Observatory at Pekin, have been brought together and published as a pamphlet in which the whole of the MS. is reproduced in facsimile. The first part of the pamphlet deals with the formulæ used in the calculation of horizontal intensity, and following it are tables showing the magnetic elements at 509 places in Europe, Siberia, and China, the longitudes and latitudes of the places being given, and also the dates of observation. Magnetic anomalies are discussed, and two local anomalies—one near the island of Ioussar-oe in Finland, and another near Moscow, are described in detail, and illustrated by three maps.

With reference to the note on p. 59 of our issue of November 18, as to the storm signals used by various maritime countries, which was based upon information contained in the U.S. Pilot Chart of the Pacific Ocean for November, we have received a note from Admiral Capello pointing out that, in addition to the use of flags of the Commercial Code and occasional semaphoric signals for the purpose of giving notice of the state of the weather between the Bay of Biscay, Madeira and Gibraltar, to passing vessels that may require it, the drum and cone signals adopted by the late Admiral FitzRoy are regularly hoisted at the semaphores to notify the probable approach of stormy weather.

The additions to the Zoological Society's Gardens during the past week include a Black-handed Spider Monkey (*Ateles geoffroyi*, ♀) from Central America, presented by Mr. F. Colsell; two White-naped Weasels (*Pœcilogale albinucha*) from South Africa, presented by Mr. W. Champion; two Flat-backed Terrapins (*Cyclemmys platynota*) from Johore, Malay Peninsula, presented by Mr. S. S. Flower; two Chameleons (*Chamæleon vulgaris*) from North Africa, presented by Mr. Horace Dibley; two Ring-tailed Coatis (*Nasua rufa*), a Kinkajou (*Cercoleptes caudivolvulus*), a Punctated Agouti (*Dasyprocta punctata*), a Globose Curassow (*Crax globicera*) from British Honduras; two Vervet Monkeys (*Cercopithecus lalandii*, ♂ ♀) from South Africa, deposited; two Scaup Ducks (*Fuligula marila*, ♂ ♀), European, purchased.

Dr. C. Börgen asks us to state that in his letter on "The Law of Divisibility," which appeared in Nature of November 18 (p. 54), he should have written $\Sigma(a_{v+a-1}$ instead of $\Sigma(a_{v-a+1}$.

OUR ASTRONOMICAL COLUMN.

Meteors (Geminids).—The interest awakened by the recent expectation of a brilliant return of the Leonid meteors may induce many to make observations of other showers. It may be well, therefore, to remember that from the 9th to the 12th inst. the fairly good shower of the Geminids takes place. The radiant point is situated near Castor in R.A. 7h. and north declination 32°. In the years 1885 and 1892 there were remarkably good displays.

o Ceti (Mira).—In this column last week reference was made to the brightness of "Mira" near its maximum. Further observations made at the Solar Physics Observatory, South Kensington, show that, as at previous times, the light curve of this star is subject to fluctuations near maximum, but the star is still about the third magnitude, being considerably brighter than γ Ceti (3·38 N.O.U.). Only visual observations of the spectrum have been possible in consequence of the troubled state of the weather, which has not allowed of the long exposures necessary to secure the violet portion of the spectrum; the visual observations show the same bands as recorded by Sir Norman Lockyer at Westgate in 1888 (Nature, vol. xxxviii. p. 61). This year the star will be well situated for observation for a considerable time after its brightest period, before being lost in the twilight, as it is now on the meridian about 9.30 p.m. We hope later to be able to give some additional facts as to the change which takes place in the invisible portion of the spectrum in passing from maximum to minimum.

The Companion of Sirius.—Prof. Burnham, using the 36-inch Lick refractor, was the last to observe the companion of Sirius before its perihelion passage. The observation was by no means an easy one, the distance being measured as 4″·19 (1890 April 22). Since that date, especially during the last two years, several observers have attempted to catch a glimpse of this body with varying results. Dr. See, in a communication on this subject (*Astr. Journal*, No. 418), points out that although several objects have been measured which were thought at the time to be the companion in question, there seems to be evidence to show that in some cases these were spurious. There is, however, no doubt that the companion can now be seen, and several measures show that it is following with great accuracy the orbit which Dr. See computed for it in his work on "Researches on the Evolution of the Stellar Systems" (vol. i. p. 84). The satisfactory agreement of the observed and computed positions shows that this orbit is of a high degree of accuracy, and will be serviceable for many years to come. The following ephemeris, taken from Dr. See's paper, gives the position angles and distances for the next three years:—

	Pos. angle.	Distance.
	°	″
1897·70	174·5	4·59
1898·20	169·0	4·72
1899·20	158·9	4·97
1900·20	149·5	5·25

A LIBERAL GIFT TO ASTRONOMY.—It was briefly announced in last week's NATURE that Miss Alice Bache Gould, daughter of the late Dr. Gould, had entrusted to the U.S. National Academy of Sciences a fund of 20,000 dollars; we are now able to state the precise conditions under which the gift was made. The money given by Miss Gould is to be known as the Benjamin Apthorp Gould Fund, and the net income of the fund is to be expended under the direction of Prof. Lewis Boss of Albany, Dr. Seth C. Chandler of Cambridge, and Prof. Asaph Hall of Washington, who are constituted by Miss Gould a board of directors for that purpose. The income is to be devoted to the prosecution of researches in astronomy by assisting observers and investigators in such manner and sums as may be agreed upon by all three of the directors.

In a letter to the directors, Miss Gould writes:—"My object in creating the fund is two-fold; on the one hand to advance the cause of astronomy, and on the other to honour my father's memory and to ensure that his power to accomplish scientific work shall not end with his own life. . . . Throughout my father's life his patriotic feeling and scientific ambition were closely associated, and I wish therefore that a fund bearing his name should be used primarily for the benefit of investigators in his own country or of his own nationality. I recognise, however, that sometimes the best possible service to American science is in the maintenance of close communion between the scientific man of Europe and of America, and that therefore, even while acting in the spirit of the above restriction, it may occasionally be best to apply this money to the aid of a foreign investigator working abroad."

One idea in the creation of the fund is that it may relieve the directors of the Bache fund of the Academy of some of their astronomical expenses, so that they may be able to devote more of their money to other departments. Miss Gould expresses a strong wish that astronomy of precision shall be distinctly preferred to work in astrophysics, first, because of Dr. Gould's personal preference, and, second, because of the existence of endowments for astrophysics. The fund is distinctly intended for the advancement and not for the diffusion of scientific knowledge; actual expenses of investigation are to be considered rather than the personal support of investigators, and the directors are advised not to cover with their grants the field provided for by existing endowments.

CORAL BORING AT FUNAFUTI.[1]

THE boring at Funafuti, according to the latest advices, had reached a depth of 643 feet. Prof. David's report is transcribed from notes made during the progress of the work, and gives his first impressions of the materials brought up, down to a depth of 557 feet, which had been reached when he quitted the island to return to his duties at Sydney, leaving the work in charge of his assistant. The latest advices informed him that the boring was arrested at 643 feet, but as it was hoped this was only for a time, we are daily expecting to hear yet more gratifying news. His last letters, received during the present week, give a few particulars of the materials pierced between 557 and 643 feet. The work, states Prof. David, often presented most serious difficulties, which would probably have frustrated their efforts, but for the experience gained on the former occasion.

The bore-hole is situated about half a mile north-east of the Mission Church, and its height above sea level is about 1 foot above high water mark at spring tides. The diameter is 5 inches down to 68 feet; it is lined with 5-inch tubing down to 118 feet, and 4-inch from surface to 520 feet, so that on September 6 a 4-inch core was being obtained.

The following is a general description of the materials pierced:—For about a yard at the top there was a hard coral breccia. This was followed down to a depth of 40 feet by "coral reef rock," into the composition of which *Heliopora cerulea*, with spines of echinids and nullipores entered largely, the last predominating over the coral at from 15 to 20 feet. From 40 to 200 feet came more or less sandy material, but with a variable quantity of corals. These were scattered through the sand (calcareous and of organic origin; foraminifera, at about 40 feet, making from one-half to two-thirds of the whole) sometimes as fragments (forming occasionally a kind of rubble), but sometimes in the position of growth. Between 120 and 130 feet, and from about 190 to 200 feet, the material is described as fairly compact coral rock, so that very probably reefs *in situ*, though of no great thickness, were pierced at these depths. The sand appears to be largely derived from coral, but foraminifera occur, sometimes in abundance; so too do nullipores, and here and there spines of echinids. Towards 150 feet signs of change begin to appear in the corals, and these become more conspicuous as the boring approaches its greatest depth. In such case, if I understand rightly, some of the branching corals crumble away and are represented only by casts, while others remain, the surrounding matrix becoming solid, cemented apparently by calcite. Below 202 feet a decided change takes place in the character of the deposit. All above this seems to be largely composed of material derived from corals, with occasional rather brief interludes of true reef; and this mass, measuring, as said above, rather over 200 feet in thickness, may be termed the first or uppermost formation. Below this, down to about 373 feet, sandy material distinctly dominates, which sometimes is almost a calcareous mud. Still even there coral fragments and rubble occasionally appear, and now and then a few isolated corals. Other organisms may be detected, including nullipores, foraminifera, and mollusca; but until this material has been examined microscopically, it would be premature to attempt any precise statement. This mass, in thickness about 170 feet, may be termed the second or middle formation. It is not reef, though obviously produced in the vicinity of a reef. Below 370 feet is the third or lowest zone; in this beds composed of broken coral become frequent, which are intercalated with masses of dead coral, though sandy bands also occur. The character of the material suggests that it has been formed in the immediate vicinity of a reef, which has occasionally grown out laterally, though only for a time, and has built up a layer of true reef, from 2 to 3 feet in thickness, upon a mass of detrital coral. In one place the rock is specially noted as "hard," and hereabouts even the shells of gastropods have perished, only their casts remaining. From 526 to 555 feet the bore passed through fairly compact and (in places) very dense and hard "coral limestone" and "cavernous coral rock," in which dendroid forms were numerous. As regards the part between 557 feet and 643 feet only brief information is to hand, but Prof. David states that it is reported to be chiefly coral limestone, hard and dense, with occasional soft bands of coral sand or coral rubble. Thus the third, or lowest zone, about 270 feet in thickness, corresponds apparently with the first, but it seems to contain larger and more numerous masses of true reef.

Prof. David has also forwarded with his latest letters a section of the boring and of the exterior form of the island, down to about 730 fathoms: the one drawn from his notebook, the other from Captain Field's record of soundings. From this I gather the following particulars:—The bore-hole is, roughly speaking, rather over 100 yards from the margin of the ocean, and about 165 yards from that of the lagoon; it is about 240 yards from the spot where a sounding of 10 fathoms was obtained, nearly 400 yards from a 36-fathom sounding, and rather more than a quarter of a mile from one of 130 fathoms. After this the submarine slope, for a considerable depth, is not quite so steep. He also states that, at Funafuti, the vigorous growing portion of the reef appeared to be limited to within about 40 feet of the surface.

---

[1] "Summary of Prof. Edgeworth David's Preliminary Report on the Results of the Boring in the Atoll of Funafuti." Communicated by Prof. T. G. Bonney, F.R.S., Vice-Chairman of the Coral Reef Boring Committee. Read at the Royal Society, November 25.

It would be premature, as Prof. David remarks, to express an opinion as to the theoretical bearing of these results until the core has been thoroughly studied. But two things seem clear, (1) that true reef has been pierced at depths down to more than 600 feet, and (2) that throughout the whole of the time represented by the mass which has been tested, coral must have grown in great abundance in some part or other of the locality now represented by Funafuti; for the atoll, it must be remembered, is surrounded by water about 2000 fathoms deep, which would completely isolate it from any other coraliferous locality.

THE VITALITY OF REFRIGERATED SEEDS.[1]

A CONSIDERABLE difference of opinion still exists amongst biologists as to the condition of the protoplasts of resting seeds, spores, &c., in which all ordinary signs of life may be unrecognisable for a considerable period.

According to one view, the essential elements of the cell, during the period of inertness, are still undergoing feeble but imperceptible alteration, accompanied by gaseous exchange with the surrounding atmosphere; and, even when ordinary respiration is in abeyance, it is assumed there are small internal changes going on, due to the interaction of certain constituents of the protoplasm, reactions which may be independent of the outside gaseous medium, and which are often referred to under the somewhat vague term of "intramolecular respiration."

On the other hand, it is sometimes maintained that all metabolism is completely arrested in protoplasm when in the dormant state, and that it then loses, for the time being, all power of internal adjustment to external conditions.

According to one view, therefore, the machinery of the dormant protoplasts is merely "slowed down" to an indefinite extent, whilst according to the other it is completely brought to rest for a time, to be once more set going when external conditions are favourable.

It appears to us that the advocates of the "slowing-down" hypothesis have scarcely given sufficient attention to the experimental evidence available, and that they have been somewhat biassed by a supposed analogy between the dormant state of seeds and the hibernating state in animals, and have also, perhaps, been unconsciously influenced by Mr. Herbert Spencer's well-known definition of life, which implies a constant internal adjustment in the living protoplasm.

The experiments of the late G. J. Romanes, which were described in a short paper laid before the Society in 1893 (*Roy. Soc. Proc.*, vol. lvii. p. 335), are full of interest in their bearing on this question. Seeds of various plants were submitted in glass tubes to high vacua of 1/1000000 of an atmosphere for a period of fifteen months. In some cases, after the seeds had been *in vacuo* for three months, they were transferred to other tubes charged respectively with oxygen, hydrogen, nitrogen, carbon monoxide, carbon dioxide, hydrogen sulphide, aqueous vapour, and the vapour of ether and chloroform. The results proved that neither a high vacuum, nor subsequent exposure for twelve months to any of the above gases or vapours, exercised much, if any, effect on the subsequent germinative power of the seeds employed.

These experiments of Romanes are certainly of the highest importance, since the seeds were submitted for a long period to conditions which must certainly have excluded anything like respiration by ordinary gaseous exchange, but the conditions did not preclude with the same certainty the possibility of chemical interactions of some kind or other within the protoplasm, those ill-understood changes, in fact, which have been referred to "intermolecular respiration." It is true that in some of the experiments, notably those in which the vapours of chloroform and ether were employed, the probability of any such internal reactions is rendered somewhat remote; but still, in most cases, the experiments admit of the possibility of feeble metabolic activity continuing in the cytoplasm.

It occurred to us, some months ago, that more evidence would probably be forthcoming on these points if we could submit seeds to a temperature below that at which ordinary chemical reactions take place, thus eliminating any possibility of interactions between the constituents of the protoplasm.

Owing to the kindness of Prof. Dewar, who has been good enough to place the resources of his laboratory at our disposal, and to undertake this part of the work for us, we have been able to ascertain how far the subsequent germinative power of a considerable variety of seeds is affected by prolonged exposure to the very low temperatures produced by the slow evaporation of *liquid air*.

The seeds, enclosed in thin glass tubes, were slowly cooled, and immersed in a vacuum-jacketed flask containing about two litres of the liquid air, which was kept replenished so as to submit the seeds for 110 consecutive hours to a temperature of from − 183° C. to − 192° C. About ten litres of liquid air were required for the experiment.

The seeds had been previously air-dried only, so contained from about 10 to 12 per cent. of natural moisture. After the above treatment they were slowly and carefully thawed, a process which occupied about fifty hours, and their germinative power was then compared with control experiments made on other portions of the seed which had not been treated in any way.

The seeds experimented on were as follows:—

Hordeum distichon.
Avena sativa.
Cucurbita Pepo.
Cyclanthera explodens.
Lotus Tetragonolobus.
Pisum elatius.
Trigonella fœnum-græcum.
Impatiens balsamina.
Helianthus annuus.
Heracleum villosum.
Convolvulus tricolor.
Funkia sieboldiana.

These include representatives of the following natural orders:—Gramineæ, Cucurbitaceæ, Leguminoseæ, Geraniaceæ, Compositæ, Umbelliferæ, Convolvulaceæ, and Liliaceæ.

Some of the seeds are endospermous, others non-endospermous, and the reserve material consists in some cases of starch, and in others of oil or of mucilage.

Their germinative power, after being submitted to the low temperature, showed no appreciable difference from that of the controls, and the resulting plants, which were in most cases grown to full maturity, were equally healthy in the two cases.

In 1892 Prof. Dewar and Prof. McKendrick found that a temperature of − 182° C. continued for one hour is insufficient to sterilise putrescent substances such as blood, milk, flesh, &c., and that seeds would germinate after the action of a similar temperature for the same period of time (*Roy. Inst. Proc.*, 1892, vol. xiii. p. 699).

When we commenced our experiments we were unaware that any other observations of a similar nature had been made, but whilst they were in progress our attention was drawn to an important memoir by C. de Candolle,[1] in which the latent life of seeds is discussed in the light of a number of low temperature experiments made principally by himself and R. Pictet, and described at intervals in the Geneva "Archives."[2] In the earlier experiments of C. de Candolle and Pictet, made in 1879, temperatures of − 39° C. to − 80° C. were employed, and these only from two to six hours, whilst Wartmann in 1881 exposed seeds for two hours to − 110° C. without effect. In 1884 Pictet found that an exposure of various kinds of Bacteriaceæ for three days to − 70° C., and afterwards for a further period of thirty-six hours to − 120°, did not destroy their vitality, and in the same year Pictet and C. de Candolle exposed seeds to − 100° C. for four days with the same result. Pictet, in 1893, further extended his observations to various microbes, and also to a large number of seeds, and claims to have cooled them down without effect to nearly − 200° C., but he gives no details of the experiments, nor any indication of the length of time during which the cooling lasted. His conclusions, however, are that, since all chemical action is annihilated at − 100° C., life must be a manifestation of natural laws of the same type as gravitation and weight.

In his memoir of 1895 (*loc. cit.*) C. de Candolle discusses very fully whether we must regard the life of the resting seed as completely arrested for a time or merely temporarily slackened (ralentie), and he gives the results of some new experiments on seeds maintained at from − 37° C. to − 53° C. in the "snow-box" of a refrigerating machine for a period of 118 days. Most of the seeds resisted this treatment successfully, and the author concludes that after a sufficient interval of time has elapsed the protoplasm of the ripe seed passes into a state of complete inertness in which it is incapable either of respiration or assimilation, and that whilst in this condition it can support, without detriment to its subsequent revival, rapid and considerable lowering of temperature.

---

[1] "Note on the Influence of very Low Temperatures on the Germinative Power of Seeds." By Horace T. Brown, F.R.S., and F. Escombe. (Read before the Royal Society, November 18.)

[1] *Archives des Sci. Phys. et Nat.*, Geneva, 1895, vol. xxxiii. p. 497.

[2] E. Wartmann, 1860, *Archives des Sci. Phys. et Nat.*, 1860, p. 277; C. de Candolle and Pictet, 1879, *ibid.*, vol. ii. p. 354: *ibid.*, vol. ii. p. 629; E. Wartmann, 1881, *ibid.*, vol. v. p. 340; R. Pictet, 1884, *ibid.*, vol. xi. p. 320; R. Pictet and C. de Candolle, *ibid.*, p. 385; R. Pictet, 1893, *ibid.*, vol. xxx. p. 293; C. de Candolle, 1895, *ibid.*, vol. xxxiii. p. 497.

De Candolle then points out that if it really be a fact that the suspended life of a resting seed is in any way dependent on respiration we might expect this to be shown by submitting seeds to a barometric vacuum for some time. He does not appear to have followed out this suggestion, and is apparently unaware of the direct experiments on this point carried out by Romanes two years previously; he argues, however, that if ordinary respiration is a factor of any importance, this may be determined by immersing the seeds in mercury for such a length of time as to ensure the complete consumption of the small amount of oxygen contained within their tissues. It was found that when seeds of *wheat*, and of *Lepidium sativum* were thus treated, for periods varying from one to three months, their power of germination was not sensibly affected.

Although these last described experiments of C. de Candolle go far to show that any considerable amount of respiration is unnecessary for the maintenance of potential life in the protoplasm of resting seeds, they are not inconsistent with the view that some minute amount of gaseous exchange may be going on during the whole course of the experiment at the expense of the oxygen contained in the seeds at the time of immersion in the mercury. The results would have been far more conclusive on this point if it had been shown that the gaseous oxygen originally contained in the seed tissue had been completely used up in an early stage of the experiment. The experiments of Romanes, however, conducted with high vacua and atmospheres of various gases, leave no room for doubt on this question, and we must consequently abandon all idea of the dormant state of resting seeds having any necessary dependence whatever on ordinary respiratory processes. Neither set of experiments, however, excludes the possibility of molecular interchanges in the protoplasm itself, such molecular transpositions in fact as those which can often be induced in living cells placed under anaerobic conditions, and which are all exothermic in character, and generally, but not necessarily, attended with the liberation of more or less CO_2. The great value of the low temperature experiments we have described lies in the fact that such processes of autoxidation, and in fact any conceivable internal chemical change in the protoplasts, are rendered impossible at temperatures of − 180° C. to − 190° C., and that we must consequently regard the protoplasm in resting seeds as existing in an absolutely inert state, devoid of any trace of metabolic activity, and yet conserving the potentiality of life. Such a state has been admirably compared by C. de Candolle with that of an explosive mixture, whose components can only react under determinate conditions of temperature; as long as these conditions remain unfulfilled the substances can remain in contact with each other for an indefinite period without combining.

It appears to us that the occurrence of a state of complete chemical inertness in protoplasm, without a necessary destruction of its potential activity, must necessitate some modification in the current ideas of the nature of life, for this inert state can scarcely be included in Mr. Herbert Spencer's well-known definition, which implies a continuous adjustment of internal to external relations.[1] The definition doubtless holds good for the ordinary *kinetic* state of protoplasm, but it is not sufficiently comprehensive to include protoplasm in the *static* condition in which it undoubtedly exists in resting seeds and spores. The definition becomes in fact one of "vital activity" rather than of life.

As it is inconceivable that the maintenance of "potential vitality" in seeds during the exposure of more than 100 hours to a temperature of − 180° to − 190° C. can be in any way conditioned by, or correlated with, even the feeblest continuance of metabolic activity, it becomes difficult to see why there should be any time-limit to the perfect stability of protoplasm when once it has attained the resting state, provided the low temperature is maintained; in other words an immortality of the individual protoplasts is conceivable, of quite a different kind from that potentiality for unending life which is manifested by the fission of unicellular organisms, and with which Weismann has rendered us familiar.

In what manner and to what extent "resting" protoplasm differs from ordinary protoplasm we do not at present know, but there are indications, notably those afforded by the resting state of desiccated Rotifera, and also by some recent experiments of Van Eyck on discontinuous germination ("Ann. Agron," vol. xxi. (1895), p. 236), that ordinary protoplasts may, by suitable treatment, be brought to the "resting" condition.

In 1871, Lord Kelvin, in his Presidential Address to the British Association, threw out the suggestion that the origin of life as we know it may have been extra-terrestrial, and due to the "moss-grown fragments from the ruins of another world," which reached the earth as meteorites.[1] That such fragments might circulate in the intense cold of space for a perfectly indefinite period without prejudice to their freight of seeds or spores, is almost certain from the facts we know about the maintenance of life by "resting" protoplasm; the difficulties in the way of accepting such a hypothesis certainly do not lie in this direction.

We must express our thanks to Mr. Thiselton-Dyer and to Dr. D. H. Scott, for the facilities they have given us in carrying out these experiments in the Jodrell Laboratory.

Addendum.

After the completion of the above Note, our attention was called to a recent investigation by M. R. Chodat, on the influence of low temperatures on *Mucor mucedo* ("Bulletin de l'Herbier Boisier," vol. iv. (1896), p. 894). He found that a lowering of temperature for several hours to − 70° to − 110° C. failed to kill young spores of the mucor, and he adduces certain evidence, which is not, however, wholly convincing, that even the mycelium itself, when cultivated on Agar Agar, and whilst in active growth, is able to resist the action of these low temperatures. The author sums up his opinion as to the bearing of his experiments on the nature of life in the following words:—"La respiration elle-même est évidemment complètement arrêtée à cette température où les corps chimiques ne réagissent plus les uns sur les autres. Si l'on considère que la vie consiste principalement en un échange continuel de substance, soit par la nutrition intracellulaire, soit par la respiration, alors il faut convenir qu'à ces temperatures basses la vie n'existe plus. C'est une fatale erreur qu'on rencontre dans presque tous les traités que la respiration est une condition nécessaire de la vie, alors qu'elle n'est qu'une des conditions de sa manifestation. La vie est conditionée par certaines structures. Les forces qui les mettent en jeu peuvent être des forces toutes physiques. Elles sont simplement les sources d'énergie qui pourront mettre la machine en mouvement."

THE LAW OF CONDENSATION OF STEAM.

At the meeting of the Institution of Civil Engineers on Tuesday, November 30, an important paper was read on "The Law of Condensation of Steam," by Prof. Hugh L. Callendar, F.R.S., and John T. Nicolson.

In the discussion of steam-engine trials it had generally been assumed that the rate of condensation of steam on a surface was practically infinite, so that any surface in direct contact with the steam was immediately heated to the saturation temperature corresponding with the pressure of the steam. It had also been supposed that the amount of condensation under any given conditions was limited, either by the resistance of the film of condensed water to the passage of heat, or by the capacity of the metal or of the circulating water to carry off the heat. In many cases condensation was diminished by films of oil or grease, or by accumulations of hair, or by other incrustations or deposits, but these were not considered in the paper.

---

[1] The following passage from the "First Principles" (Section 25) clearly shows that the author in constructing his definition had not anticipated the possibility of a *living organism* attaining a state of absolutely stable equilibrium. "All vital actions, considered not separately but in their *ensemble*, have for their final purpose the balancing of certain outer processes by certain inner processes. There are unceasing external forces tending to bring the matter of which organic bodies consist into that state of stable equilibrium displayed by inorganic bodies; there are internal forces by which this tendency is constantly antagonised, and the perpetual changes which constitute life may be regarded as incidental to the maintenance of the antagonism."

[1] We find that Prof. Dewar called attention in one of his Royal Institution lectures in 1892 to the bearing of his low temperature experiments with spores, &c., on this suggestion of Lord Kelvin's (see *Roy. Inst. Proc.*, 1892, vol. xiii. p. 699.)

The authors found, on the contrary, as the result of their experiments on a steam-engine running under normal conditions, that a practically clean and dry metal surface was not immediately heated to the temperature of the saturated steam in contact with it, that the rate of condensation of steam was not infinite, but finite and measurable, and that the amount of condensation in any given case was limited chiefly by this finite rate of condensation, and could be calculated in terms of it.

The cyclical variations of temperature in the metallic walls of the cylinder, with each stroke of the engine, were measured by means of thermo-couples inserted at various distances from the inner surface. It was possible thus to deduce the amount of heat absorbed and given out by the metal, and to infer the quantity of steam condensed and re-evaporated at different points of the stroke. The temperature-cycles of the steam were simultaneously measured by a very sensitive platinum thermometer. The observations showed that the temperature of the steam in different parts of the cylinder differed in a systematic way from the saturation temperature as deduced from indicator diagrams.

In order to deduce the condensation from the observed temperature-cycles, it was necessary to determine the conductivity and specific heat of cast iron. A series of experiments were made upon a four-inch bar of cast iron, and the result found for the conductivity was nearly 30 per cent. smaller than that generally assumed.

At the lowest speed of the experiments, namely, forty-five revolutions per minute, the temperature of the surface of the metal at the end of the admission period was found to be never raised higher than within 20° F. of the temperature of the steam, and the rate of condensation at any moment was simply proportional to the difference between the temperature of the steam and the surface. The numerical value found for the rate of condensation was 0·74 B.T.U. per second per square foot of surface per degree Fahrenheit of difference between the temperature of the steam and the surface. This was equivalent to the condensation of 27 pounds of steam per square foot per hour at 300° F., for a difference of temperature of 10° F. Assuming this law, the total amount of condensation at any point of the stroke could be inferred by measuring the "Condensation Areas" on the temperature-cycle diagram, *i.e.* the areas included between the curves representing the temperatures of the steam and of the metal surface.

To compare the results thus found with the missing steam deduced from the indicator diagrams and the feed measurements, the leakage of the valve and piston was determined as nearly as possible under the conditions of running. It was found to be proportional to the difference of pressure and nearly independent of the speed through a considerable range. The usual test for leakage with the valve stationary was found to be of little or no value. From a comparison of leakage tests, it was inferred that a valve in motion, however well fitted, was subject to leakage of a definite type. The leakage took place chiefly in the form of water, by condensation and re-evaporation on the moving surfaces, and was directly proportional to the perimeter of the ports and inversely to the width of the bearing surfaces. The amount of condensation observed during the admission period in a single-acting non-condensing cylinder 10·5 inches in diameter with a stroke of 12 inches, was only 20 per cent. of the feed at a speed of 100 revolutions per minute. The smallness of this result was probably due to the early compression and the dryness of the steam supply. It was found that re-evaporation was completed very quickly, and that the walls were dry for the greater part of the cycle. It was inferred from the form of the temperature curves and from other evidence that the rate of re-evaporation was the same as that of condensation.

From the form of the law of condensation it was possible to make an important theoretical deduction with regard to cases in which re-evaporation was incomplete, and the walls remained wet throughout the whole cycle. Under these conditions the mean temperature of the walls should be the same as the time average of the temperature of the steam to which they were exposed, and the cyclical condensation was the maximum possible for the given steam cycle. If the extent of the clearance surfaces was known, this limiting value of the condensation in any case might be easily deduced from the indicator diagram. If the surfaces were dry during part of the stroke, the condensation was less than the limit, and it was necessary to know the mean temperature of the clearance surfaces in addition. Upon these views of the nature of condensation and leakage, the missing quantity of steam W in pounds per hour might be expressed by an equation of the general type, $W = S\,(t' - t^{\circ}) + L\,(p' - p'')$,—where the first term represented condensation and the second term leakage, S being the equivalent clearance surface in square feet, and $t' - t^{\circ}$ the mean difference of temperature, in degrees Fahrenheit, between the walls and the steam during admission reduced to one-half cut-off. L, the rate of leakage per pound difference of pressure $p' - p''$, might be taken to vary approximately as the product of the diameter and the square root of the normal piston-speed, for engines of different sizes. It would appear from this formula that the effect of leakage on the performance was relatively more important in small engines and at high pressures, and that the loss due to condensation was most effectively reduced by increase of piston-speed.

As an indirect verification of this law of condensation, the temperature of the clearance surface in cases in which water was present in the cylinder was measured, and was found to agree with that of the mean of the steam cycle. The amount of condensation was also correctly calculated in several cases of published tests in which sufficient data were available. The rate of condensation deduced was also directly verified by an entirely different method. The experiments gave approximately the same rate of condensation, and appeared to show that the water-drops condensed on the metallic surface, owing probably to their rapid action, did not appreciably diminish the rate. Assuming it possible to estimate the condensation occurring in any given case by the method indicated, from a knowledge of the indicator diagram and of the temperature and area of the clearance surfaces, it then became possible to determine the amount of leakage under the actual conditions of running.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Institution of Civil Engineers has resolved to exempt Bachelors of Arts who obtain honours in the Mechanical Sciences Tripos from the examination prescribed for the Associate Membership of the Institution.

The Managers of the John Lucas Walker Studentship have elected Mr. J. W. W. Stephens, of Caius College, to the studentship in Pathology, and Dr. Hamilton K. Wright, of McGill University, Montreal, to an Exhibition of the value of 50*l.*

The proposal to authorise the Examiners for the Natural Sciences Tripos Part II. to inspect the laboratory note-books of candidates for honours was carried in the Senate by forty-seven votes to eighteen.

Dr. H. A. Giles has been elected to the Professorship of Chinese. Dr. W. H. R. Rivers, of St. John's College, has been appointed University Lecturer in Physiological and Experimental Psychology. Mr. W. L. H. Duckworth, Fellow of Jesus College, has been recognised as a Lecturer in Anthropology.

The Walsingham Medals for research in Biology, including Physiology, have been awarded to Mr. V. H. Blackman, of St. John's College, and Mr. W. M. Fletcher, of Trinity College. The electors report that the essays of four other candidates were of a high order of merit.

The election to the Isaac Newton Studentship in Astronomical Physics will be held in the Lent Term 1898. Candidates must be Bachelors of Arts of less than twenty-five years of age on January 1. The studentship is of the value of 200*l.* a year for three years. Applications are to be sent to the Vice-Chancellor between January 14 and 24.

The University delegates to the International Congress of Hygiene at Madrid, next April, are Dr. Kanthack, Dr. D. MacAlister, and Dr. Anningson.

THE death is announced of Dr. Brownless, Chancellor of Melbourne University.

DR. H. H. HOFFERT has been promoted to a senior inspectorship under the Science and Art Department, and Mr. S. J. Cartlidge—at present head-master of the Hanley School of Art—has been appointed to the vacant inspectorship.

THE London Technical Education Board will proceed in July next to award three junior scholarships in practical gardening, which will be tenable at the new School of Practical Gardening which has recently been opened at the gardens of the Royal Botanic Society in Regent's Park. This school has been established with the view of providing a complete course of instruction for lads who desire to become gardeners. The scheme of work, which has been drawn up by the Royal Botanic Society, combines thorough practical instruction in all the operations of gardening with theoretical instruction in botany and the nature of soils and manures. The course is arranged so as to extend over three years.

THE list of entrance scholarships and exhibitions awarded at Pembroke, Gonville and Caius, King's, Jesus, Christ's, and Emmanuel Colleges, Cambridge, affords an indication of the comparative encouragement given to classics and science at the University. It appears from the list that the scholarships for classics have the value of 1360*l.* Mathematics comes second with scholarships amounting to the value of 640*l.*, and the natural sciences take the last place with scholarships having a total value of 390*l.* Considering that the Science Tripos is the largest, or nearly the largest, this seems a discouraging division of the scholarship fund. It is only fair to add that at Trinity and St. John's Colleges the authorities are far more liberal to science, the value of scholarships awarded for natural sciences at the former College being 330*l.*, and at the latter, 205*l.*

THE *Times* of Monday contains a detailed report of a conference held on Saturday last at the rooms of the Society of Arts, Adelphi, to consider the expediency of further development in the constitution of the Royal Holloway College in the light of the founder's expressed desire that powers should ultimately be sought enabling the college to confer degrees on its students. Mr. Bryce, M.P., one of the governors of the college, presided, and there was a large and influential gathering of educationists. Papers were read by Mr. R. D. Roberts in favour of an application from Holloway College for a separate charter to enable it to confer degrees upon its students; by Mr. Strachan Davidson, of Balliol College, Oxford, in support of the establishment of a women's university, of which Holloway College should form a part; and by Mrs. Bryant in advocacy of the proposal that Holloway College should become an integral member of the new teaching University of London. A number of letters from prominent educationists were read, expressing their views on the subject. A discussion followed, in which Mrs. Henry Fawcett, Miss Emily Davies, Mrs. Sidgwick, of Newnham, Miss M. Gurney, Sir Joshua Fitch, Mr. H. Sidgwick, and others took part. There was a practical consensus of opinion against the proposal that Holloway College should give degrees; a great majority of the speakers were opposed to the creation of a separate University for women, and many of them were in favour of connection with the new London University.

THE new Academic Hall of Edinburgh University, opened on Saturday last, is another testimony to the close and friendly connection which has always existed between the University and the city. In 1888, Mr. William M'Ewan, M.P. for the Central Division of Edinburgh, offered a sum of 40,000*l.* with which to build the Academic Hall, which had formed a part of the original plans of the new University buildings, which had already cost 250,000*l.* to complete. This offer Mr. M'Ewan afterwards, on its being made clear that the amount was inadequate if the hall was to be proportionate to the buildings already erected, agreed to increase to 62,000*l.*, which was the original estimate of the cost of the hall. As the scheme grew under the hands of the architect, artificers, decorators, and organ builders, the liberality of Mr. M'Ewan kept pace, and the hall, as it now stands completed, has cost him 115,000*l.* The gift is a noble one, and it provides a noble example of the interest which the citizens of Edinburgh take in the welfare of the University. In accepting the deed of conveyance, on behalf of the University, Mr. Balfour said: "I confess that I have seen with feelings of regret, sometimes almost amounting to shame, the extreme difficulty which there has been not merely in connection with Edinburgh, but in connection with other great seats of learning, to obtain from the liberality of a not illiberal public sufficient means to make our great British Universities all that British Universities should be. I fear that in this respect we can but ill stand comparison with our cousins of the United States. There, if my information is not incorrect, they have never failed to find men with the means and with the will to keep the institutions of higher education in their country abreast with the ever-growing necessities of such institutions; and the number of generous benefactors which America has been able to show may well cause some feeling of shame, I think, in us on this side of the Atlantic, speaking the same language, possessing the same culture, aiming at the same objects, but who have not always shown in pursuit of those objects the same uninterested generosity. The relations between Edinburgh and the University, always close, almost always friendly, have not been diminished by changes in the status of the University. In connection with this very hall, or rather with the surroundings and accessories to the hall, the city of Edinburgh has shown itself possessed of the same generous public spirit, the same desire to do everything in its power to promote the interests of this great seat of learning which it has shown throughout all the centuries since this University was first founded." Mr. M'Ewan's liberality and Mr. Balfour's remarks upon the relations between the city of Edinburgh and the University should furnish food for reflection to the citizens of London.

THE *Technical Education Gazette* publishes a few particulars with regard to the entries in the various classes at the nine polytechnics which are in receipt of aid from the Technical Education Board of the London County Council. The most significant fact in connection with the polytechnics is that, notwithstanding the opening of four new large polytechnics during the four years that the Board has been at work, no diminution has been caused in the number of students attending the older institutions, but on the contrary, every one of the nine institutions shows an increase in the number of class entries for the present session. Thus the remarkable result has been brought about that, although these four new institutions show this session a total of over 8000 class entries, representing a total number of nearly 5000 individual students, yet the enrolment of these new students has not only not decreased the membership of the other older institutions but has actually stimulated their growth. It may be estimated that there are now in attendance at the evening classes of the nine polytechnics about 18,000 individual students, the great majority of whom are engaged in systematic courses of evening instruction under the direction of the principal of the institution where they are studying. If we take the class entries in detail according to the various branches of study, we find that the classes in the building trades show in almost every case an increase in the number of students. In the engineering trades there is likewise a very general increase in the attendance at the classes. The great demand that exists for evening instruction in electrical engineering is shown by the fact that in both the two polytechnics in the south-west district of London, the Battersea Polytechnic and the South-west London Polytechnic at Chelsea, the number of students has increased during the past year with remarkable rapidity. Another satisfactory instance of increase is shown in the classes in typography and letterpress printing. Perhaps the most remarkable fact of all is that the original polytechnic at Regent Street, which draws its students from all parts of the metropolis, and which might therefore have been expected to suffer from the growth of new institutions, continues not only to maintain its numbers but even shows a further increase on last year. Last year the number of individual students attending on November 1 was 5583; this year there were in attendance on November 1 as many as 5848, representing an increase of about 5 per cent. A very rapid development has taken place in the classes at the South-west London Polytechnic. So numerous are the entries this session for both the day and the evening departments, that the resources of the building are taxed to the utmost, and very serious inconvenience is being caused in some of the departments by the want of sufficient accommodation.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 18.—"Account of a Comparison of Magnetic Instruments at Kew Observatory." By Dr. C. Chree, F.R.S., Superintendent.

Last July, M. T. Moureaux, of the Parc Saint-Maur Observatory, near Paris, brought over to England the travelling instruments employed in his magnetic survey of France, and a comparison was made between these and the standard magnetic instruments at Kew Observatory.

The comparison serves to connect the standard instruments at Kew Observatory with the standard French instruments at Parc Saint-Maur, the latter, as M. Moureaux has had the goodness to inform the author, being in excellent agreement with his travelling instruments. Parc Saint-Maur may be regarded as the base station for M. Moureaux's great survey of France and Algeria. M. Moureaux's observations occupied the afternoon of July 26, and the forenoons of July 27, 28 and 29. On the afternoons of the last three days, observations were made with the Kew standard instruments by Mr. T. W. Baker, chief assistant at the Observatory. The observations, being made at different hours of the day, had to be connected through the intermediary of the curves from the self-recording magnetic instruments.

The means of the declination and inclination readings from the Kew instruments exceeded the means from M. Moureaux's instruments by 0′·5 and 2′·0 respectively, but the mean horizontal force reading from the Kew instrument was lower than M. Moureaux's by ·00012 C.G.S. unit. In calculating the last-mentioned element, M. Moureaux made use of new values of the constants of the French instruments, to be put into general use after January 1, 1898.

The comparison is utilised to extend a table ("Brit. Assoc. Report for 1896," p. 97) in which Prof. Rücker and Mr. W. Watson embodied the results of their comparison of the standard instruments at various English and Irish observatories, made by means of travelling instruments in 1895.

The results may be summarised as follows:—

Observatory	Departures from imaginary mean instrument of the five Observatories		
	Declination	(Hor. force) × 10^6 C.G.S. units	Inclination
Kew	+ 0′·2	− 1	+ 0′·2
Parc Saint-Maur.	− 0′·3	+ 11	− 1′·8
Falmouth	+ 1′·0	+ 17	+ 1′·8
Stonyhurst ...	− 0′·9	+ 5	− 2′·0

"On *Spencerites*, a new Genus of Lycopodiaceous Cones from the Coal-measures, founded on the *Lepidodendron Spenceri* of Williamson." By D. H. Scott, F.R.S.

The fossils which form the subject of the present paper are Cryptogamic strobili, showing evident Lycopodiaceous affinities, but differing in important points from other fructifications of that family, so that it appears necessary to establish a new genus for their reception.

Two species are described, one of which (*Spencerites insignis*) is already known to us from the investigations of Williamson, who named it first *Lepidostrobus insignis*, and afterwards *Lepidodendron Spenceri*, while the other (*Spencerites majusculus*) is new.

In one of his latest publications, Williamson pointed out that it might ultimately be necessary to make his *Lepidodendron Spenceri* the type of a new genus. The separation thus suggested is now carried out, on the basis of a renewed investigation of the structure of this fossil.

Spencerites insignis is a pedunculate strobilus; the vegetative organs are not as yet identified. The specimens are calcified, and their structure admirably preserved.

The anatomy of the axis is of a simple Lycopodiaceous type, but differs in details (such as the course of the leaf-trace bundles) from that of the axis of *Lepidostrobus*. The peduncle bears sterile bracts, similar to the sporophylls of the cone itself; the latter are arranged spirally, or in some cases in alternating verticils.

The individual sporophylls are of peltate form, consisting of a short cylindrical pedicel, expanding into a relatively large lamina. The sporangia are approximately spherical bodies; unlike those of *Lepidostrobus*, they are quite free from the pedicel, and are attached by a narrow base to the upper surface of the lamina, where it begins to expand.

The details of the sporangial wall are quite different from those of *Lepidostrobus*, and the spores are also characteristic. In size they are intermediate between the microspores and macrospores of *Lepidostrobus*. They are of tetrahedral form, becoming spheroidal when mature, and each spore has a hollow, annular wing running round its equator. The wing is no doubt formed by a dilation of the cuticle, and not, as Williamson supposed, from the abortive sister-cells.

Spencerites majusculus, the new species, is much larger than the former, the axis of the cone being twice as thick. The anatomy is similar, but the sporophylls, and consequently the leaf-traces, are more numerous. The sporophylls, which are arranged in alternating verticils, are relatively short, and of peculiar form; the lamina is very thick, and of great tangential width. The sporangia are like those of the former species, and similarly inserted, but the spores are quite different. They are smaller than those of *S. insignis*, and have the form of quadrants of a sphere, with narrow wings along their three angles.

The genus is separated from *Lepidostrobus*, mainly on account of the very different mode of insertion of the sporangia, a character which is accompanied by differences in the form of the sporophylls and sporangia, the structure of the sporangial wall and of the spores, and the whole habit of the strobilus.

Spencerites, and especially *S. insignis*, bears a considerable resemblance to the *Sigillariostrobus Crepini*, of Zeiller, but cannot be united with the genus *Sigillariostrobus*, for the insertion of the sporangia in the latter, as shown in the *Sigillariostrobus ciliatus*, of Kidston, is totally different. The author is much indebted both to M. Zeiller and Mr. Kidston, for the loan of their specimens for examination.

Zoological Society, November 30.—Mr. E. T. Newton, F.R.S., in the chair.—Mr. Oldfield Thomas exhibited specimens of a remarkable partially white Antelope of the genus *Cervicapra*, which had been obtained by Mr. F. V. Kirby in the mountains of the Lydenburg district of the Transvaal, and read an account of them contributed by Mr. Kirby himself. Mr. Oldfield Thomas also exhibited a skin of a new Skunk of the genus *Spilogale* from Sinaloa, Mexico, proposed to be termed *Spilogale pygmaea*. It was interesting as being of barely half the size of any previously known species, and also differed from all its congeners in the median dorsal stripes being uninterrupted posteriorly, and in having white hands and feet.—Mr. Thomas likewise exhibited a Badger from Lower California, proposed to be termed *Taxidea taxus infusca*, which differed from the described forms of *T. taxus* in its dark coloration and broad nuchal stripe.—Mr. Sclater exhibited the head of a *Capra* from Arabia, which had been recently described as *Capra mengesi*. Mr. Sclater was inclined to believe that the specimen was referable to *Capra sinaitica*, in which opinion Mr. O. Thomas agreed with him.—Mr. R. E. Holding exhibited a pair of curiously deformed horns of the Fallow Deer, and made remarks on the associations between organic disease and defective horn-growth.—On behalf of Mr. R. Lydekker was exhibited a skin and antlers of a small form of the Mule Deer from Lower California, for which he suggested the name *Mazama hemionus peninsulae*. It differed from *M. h. californicus* in its small size, black dorsal line, and in the reduction of white on the tail.—Mr. G. A. Boulenger, F.R.S., exhibited some specimens of a South-American Siluroid Fish (*Vandellia cirrhosa*), and made remarks upon its curious habits.—A communication from Mr. H. H. Brindley, on regeneration of the legs in *Blattidae*, was read. It consisted of an account of the statistical and experimental evidence of the reproduction of lost or injured legs in the *Blattidae*, obtained since the publication of Mr. W. Bateson's book, "Materials for the Study of Variation," in 1894, and of some points in the post-embryonic development of the Cockroach (*Periplaneta orientalis*).—Mr. G. A. Boulenger, F.R.S., read a paper on a gigantic Sea-perch, *Stereolepis gigas*. This fish was described both externally and internally, and the author pointed out that *Megaperca ischinagi*, Hilgendorf, was specifically identical with it. Mr. G. A. Boulenger also described a new Tortoise of the African genus *Sternotherus*, a specimen of which had lately been received at, and was still living in, the Society's Gardens. It was proposed to name it *Sternotherus oxyrhinus*.—A communication from Mr. W. E. Collinge, on the structure and affinities of some further new species of slugs from Borneo, was read. Three new species, namely, *Parmarion fultoni*, *P. flavescens*, and *Microparmarion constrictus*, were described, and the author intimated that Simroth's genus *Microparmarion* would, on examination of more material, probably be found to be of only sectional value.

EDINBURGH.

Mathematical Society, November 12.—Mr. J. B. Clark, Vice-President, in the chair.—Prof. George A. Gibson contributed a paper on the "Treatment of Arithmetical Progressions by Archimedes," and communicated a paper by M. Lémeray, entitled "Quatrième Algorithme Naturel." The following were elected office-bearers for the current session:—President, Mr. J. B. Clark; Vice-President, Dr. Alexander Morgan; Hon. Secretary, Mr. J. W. Butters; Hon. Treasurer, Mr. D. Tweedie; Editors of *Proceedings*, Mr. W. J. Macdonald, Dr. Knott, Mr. Charles Tweedie; Committee, Messrs. G. Duthie, R. F. Muirhead, and J. D. H. Dickson.

MANCHESTER.

Literary and Philosophical Society, November 30.—Mr. J. Cosmo Melvill, President, in the chair.—Mr. H. W. Freston (Prestwich) and Mr. C. E. Stromeyer (Manchester) were elected ordinary members of the Society.—The President announced that the Council had awarded the Wilde Gold Medal of the Society for 1898 to Sir Joseph Dalton Hooker, C.B., K.C.S.I., F.R.S., in recognition of his eminent services to all branches of botanical science; and had awarded the Dalton Medal of the Society (struck in 1864) for 1898 to Dr. Edward Schunck, F.R.S., for his remarkable series of researches on the natural colouring matters; also. that the premium for 1898 of fifteen guineas had been awarded to Mr. John Butterworth, of Shaw, for his paper, printed in the *Manchester Memoirs*, on some further investigations of fossil seeds of the genus *Lagenostoma* (Williamson).—Prof. H. Lamb read a paper entitled "On waves in a medium having a periodic discontinuity of structure." The main object of the paper is to examine the selective total reflection which takes place at the boundary of a medium of this character. In the examples chosen for discussion the medium is represented by a string supposed to be capable of longitudinal vibrations, and the periodic interruption of properties may consist in a series of attached masses, or of attached particles, which are, moreover, urged towards fixed positions by springs, or to particles connected with the string by loose springs. The same analysis applies to media constituted in many other ways, and it is further shown how the methods may be adapted to cases where dynamical systems of a much more general character are interpolated at regular intervals. There are some instructive contrasts between the results obtained in the special cases above enumerated; in particular, in the last-mentioned case (that of particles attached by loose springs) it appears that relatively short waves may be transmitted freely unless the wave-length happens to fall within certain narrowly defined intervals. We have here, perhaps, an illustration of the theory of refraction sketched by Sir George Stokes in the Wilde Lecture; but some caution is, of course, necessary in drawing inferences as to theories of radiation and absorption from the study of a one-dimensional model.

PARIS.

Academy of Sciences, November 29.—M. A. Chatin in the chair.—New method of preparing carbides by the action of calcium carbide upon oxides, by M. Henri Moissan. Calcium carbide reacts with many metallic oxides at the temperature of the electric furnace, giving the carbide of the metal and lime, the latter being again partially converted into carbide by the carbon of the crucible. The carbides of aluminium, manganese, chromium, molybdenum, tungsten, titanium, and silicon were obtained by this method. The oxides of lead, bismuth and tin gave the pure metals on similar treatment.—Experimental typhoid infection, produced by the introduction of a virulent culture into a Thiry cavity, by MM. R. Lépine and B. Lyonnet.—M. Ditte was elected a Member in the Section of Chemistry, in the place of the late M. Schützenberger.—Report on a memoir of M. Le Roy, entitled "On the integration of the equations of heat."—Observations of the new planet Villiger (1897, November 19) made at the Observatory of Algiers, by MM. Rambaud and Sy.—On two occultations of the Pleiads by the moon, by M. Lagrula. The observations are utilised for the determination of the semi-diameter and parallax of the moon at its mean distance.—Employment of the method of least squares to reveal the presence of systematic errors, by M. Jean Mascart. The determination of the vertical by means of the meridian circle is subject to errors much larger than would follow from the possible error of each microscope reading. With a view to see how far these fluctuations were due to alterations of temperature, a series of fifty determinations was made, giving fifty equations of condition for each microscope for three unknowns, the deviations being assumed as a quadratic function of the temperature. The results showed, however, that the fluctuations due to temperature changes are extremely small, and that the comparatively large errors observed must be due to other causes.—Observations of the sun made at the Observatory of Lyons, with the Brunner equatorial, during the third quarter of 1897, by M. J. Guillaume.—Influence of altitude and of heat upon the decomposition of oxalic acid by sunlight, by M. J. Vallot and Mme. Gabrielle Vallot. It has been found that, although oxalic acid is practically undecomposed by heat alone, the velocity of the reaction with actinic light is very greatly accelerated by a rise of temperature. Thus two solutions of oxalic acid exposed to sunlight under similar conditions, except that one was maintained 12° higher than the other, gave decompositions of 10 and 50 per cent. respectively. The rate of decomposition also increased rapidly with the altitude.—On the fundamental theorem of projective geometry, by M. H. G. Zeuthen.—On the equation to periods, by M. X. Stouff.—On the Bessel functions $S^n(x)$ and $O^n(x)$, by M. L. Crelier.—On the statical and dynamical explosive potentials, by M. R. Swyngedauw. A reply to some criticisms of M. Jaumann.—A simple method of proving the change of period of sodium light in a magnetic field, by M. A. Cotton. A flame feebly tinged with sodium is observed through another flame also containing sodium. The edges of the second flame appear to be black, owing to its gaseous envelope being absorbent. Any small change in the period of vibration of the more distant flame, produced by the action of the magnetic field, suppresses the absorption, and causes the black border of the interposed flame to disappear. In this way it is easily shown that a change of period of light emitted parallel to the lines of force, completely extinguishes the dark border, whilst with observations made perpendicularly to the lines of force, the border grows lighter on completing the circuit round the magnet, but does not completely disappear.—Osmotic researches on very dilute solutions of cane sugar, by M. Ponsot. The author was successful in making membranes impermeable to sugar. With these measurements of osmotic pressure were made of sugar solutions containing only 1·235 and 0·6175 grams per litre. The mean of the observed pressures was exactly equal to that calculated by the Van t' Hoff formula, on the assumption that no dissociation of the sugar took place, or the coefficient $i = 1$.—On the alcoholic isocyanurates and the constitutional formula of cyanuric acid, by M. Paul Lemoult. The heats of combustion of methyl and ethyl isocyanurates were determined, and the conclusion drawn that isocyanuric acid has a ring-shaped constitution, a symmetrical tricarbimide.—Quinones and hydroquinones, by M. Amand Valeur. Determinations of the heats of combustion of toluquinone, thymoquinone, hydroquinone, hydrotoluquinone, and hydrothymoquinone.—On the transformation of sorbite into sorbose by the *Mycoderma vini*, by M. A. Matrot. The best experimental conditions for the production of sorbose from sorbite by means of the yeast *Mycoderma vini* are worked out in detail.—On the germinative plates of the Coleoptera, by M. A. Lécaillon. For certain Coleoptera it is shown that the blastula stage does not appear in development, the gastrula stage following immediately upon segmentation, and showing no typical invagination.—On the *Rouget*, a human parasite, by M. Brucker. This parasite, which appears as a parasite to man in August and September, is shown to be probably the larva of *Trombidium gymnopterorum*.—On the culture of the nostoch in presence of glucose, by M. Raoul Bouilhac.—On the characteristics of nerve and muscle stimulation, by M. G. Weiss. A reply to the criticisms of M. Dubois. The author claims that the experiments cited by M. Dubois are in reality confirmatory of his views.—Analysis of vocal sounds by the phonograph, by MM. Marichelle and Hémardinquer. In spite of the various influences which act upon the form of the period, such as musical pitch, intonation, intensity, and individual conformation of the sounding organ, each vowel is distinguished by certain invariable characters, constituting it a real individual.—On the absorption of organic materials by roots, by M. Jules Laurent. Experiments were made with maize upon solutions of glucose and invert sugar, and in every case a certain quantity of the sugar was absorbed by the roots, the amount of which appeared to be proportional to the dry weight of the plant. The sugars are utilised by the plant, and in great part excreted as carbon dioxide.—The favourable times in the treatment of black rot, by M. A. Prunet. A treatment with copper salts applied immediately after one invasion of the disease, acts beneficially against a future invasion, the maximum effect being produced by treating the vine from five to eight days after the first appearance of the spots.—On the rational construction of mills with metallic rollers, by M. J. Schweitzer.—On the analysis of silicates, by M. A. Leclère. The conditions are prescribed under which silicates may be safely opened up in a platinum crucible by means of lead oxide, the chief points being the purity of the oxide, and the complete exclusion of reducing gases by the use of a muffle.—On some peculiar circumstances which appear to have accompanied the fall of a meteorite on April 9, 1891, at Indarck in Transcaucasia, by M. Stanislas Meunier.—On the contamination of the springs of Sauve (Gard), by M. E. A. Martel. The contamination of the water supply of Sauve by sewage was proved directly by means of fluorescin. The frequent epidemics which have decimated this town are thus explained.—On two radiographs of the thorax, by M. F. Garrigou.

DIARY OF SOCIETIES.

THURSDAY, December 9.

Royal Society, at 4.30.—On the Densities of Carbonic Oxide, Carbonic Anhydride, and Nitrous Oxide: Lord Rayleigh, F.R.S.—On the Application of Harmonic Analysis to the Dynamical Theory of the Tides. Part II. On the General Integration of Laplace's Dynamical Equations: S. S. Hough.—A Note on some Further Determinations of the Dielectric Constants of Organic Bodies and Electrolytes at Very Low Temperatures: Prof. Dewar, F.R.S., and Prof. Fleming, F.R.S.—On Methods of making Magnets independent of Changes of Temperature, and some Experiments upon Negative Temperature Co-efficients in Magnets: J. R. Ashworth.—The Electric Conductivity of Nitric Acid: V. H. Veley, F.R.S., and J. J. Manley.—On the Calculation of the Co-efficient of Mutual Induction of a Circle and a Coaxial Helix, and of the Electromagnetic Force between a Helix and a Coaxial Circular Cylindrical Sheet: Prof. J. V. Jones, F.R.S.—On the Refractivities of Air, Nitrogen, Argon, Hydrogen, and Helium: Prof. W. Ramsay, F.R.S., and M. W. Travers.

Mathematical Society, at 8.—The Construction of the Straight Line joining Two Given Points: Prof. W. Burnside, F.R.S.—A Theorem concerning the Special Systems of Point Groups on a Particular Type of Base Curve: Miss F. Hardcastle.—A General Type of Vortex Motion; R. Hargreaves.—Note on a Property of Hessians: H. F. Baker.

Institution of Electrical Engineers, at 8.—Annual General Meeting.

FRIDAY, December 10.

Physical Society, at 5.—An Exhibition of an Apparatus for Self-acting Temperature Compensation of a Standard Cell: Albert Campbell.—On Lord Kelvin's Absolute Method of Graduating Thermometers: Rose Innes.

Royal Astronomical Society, at 8.—Occultation of Ceres by the Moon on 1897 November 13, observed at the Hamburg Observatory: G. Rümker.—A Determination of the Latitude Variation and of the Constant of Aberration from Observations made at the Royal Observatory, Cape of Good Hope, 1892–94: W. H. Finlay.—The Binary Star *h* 5014: R. T. A. Innes.—Mean Areas and Heliographic Latitudes of Sun-spots in the Year 1895, deduced from Photographs taken at the Royal Observatory, Greenwich, at Dehra Dûn (India) and in Mauritius.

Malacological Society, at 8.—A Description of a Supposed New Species of *Monodonta* (*Austrocochlea*) from Tablas Island: G. B. Sowerby.—On a New Species of *Amphidromus* from the Malay Archipelago (Alor Island): Hugh Fulton.—On a New Species and Probable New Sub-Genus of *Endodonta* from Ceylon, collected by O. Collett: Lieut.-Colonel H. H. Godwin-Austen, F.R.S.—Notes on a Second Collection of Marine Shells from the Andaman Islands, with Descriptions of New Forms: J. Cosmo Melvill and E. R. Sykes.—On a Small Collection of Marine Shells from New Zealand and Macquarie Island, with Descriptions of New Species: E. A. Smith.

SATURDAY, December 11.

Essex Field Club (at Chingford), at 6.30.—Notes on the Conference of Delegates of Corresponding Societies of the British Association at Toronto: Prof. Meldola, F.R.S.—Two Essex Minerals: T. S. Dymond and F. W. Maryon.

SUNDAY, December 12.

Sunday Lecture Society, at 4.—Colour: Dr. C. W. Kimmins.

MONDAY, December 13.

Society of Arts, at 8.—Gutta-Percha: Dr. Eugene F. A. Obach.

Imperial Institute, at 8.30.—Canada's Metals: Prof. W. C. Roberts-Austen, C.B., F.R.S.

TUESDAY, December 14.

Zoological Society, at 8.30.—On the *Lepidosiren paradoxa* from the Amazon: Dr. E. A. Goeldi.—On a Small Collection of Lepidoptera made by Mr. F. Gillett in Somaliland: Dr. A. G. Butler.—On the Mammals obtained by Mr. A. Whyte in N. Nyasaland, and presented to the British Museum by Sir H. H. Johnston, K.C.B.; being a Fifth Contribution to the Mammalogy of Nyasaland: Oldfield Thomas.—On a New Genus and Species of *Acaridea*: Rev. O. Pickard Cambridge, F.R.S.

Institution of Civil Engineers, at 8.—The Great Land-Slides on the Canadian Pacific Railway in British Columbia: Robt. B. Stanton.

Royal Statistical Society, at 5.30

Royal Photographic Society (Society of Arts, John Street, Adelphi), at 8.—Colour Photography: Prof. Gabriel Lippmann.

WEDNESDAY, December 15.

Society of Arts, at 8.—The Purification of Sewage by Bacteria: Dr. Samuel Rideal.

Geological Society, at 8.—On the Pyromerides of Boulay Bay, Jersey: John Parkinson.—The Exploration of the Ty Newydd Cave, Ffynnon Beuno, North Wales: Rev. G. C. H. Pollen.

Royal Meteorological Society, at 7.30.—Daily Values of Non-Instrumental Meteorological Phenomena in London, 1763–1896: R. C. Mossman.—The Rainfall of Seathwaite, Borrowdale, Cumberland: William Marriott.

Chemical Society (Extra Meeting), at 8.30.—Kekulé Memorial Lecture: Prof. F. R. Japp, F.R.S.

Royal Microscopical Society, at 8.—A New Form of Photomicrographic Camera and Condensing System: E. B. Stringer.

THURSDAY, December 16.

Royal Society, at 4.30.

Linnean Society, at 8.—On the Affinities of the Madreporarian Genus Alveopora: H. M. Bernard.—On West Indian Characeæ collected by T. B. Blow: H. and J. Groves.

Chemical Society, at 8.—Stereo-Chemistry of Unsaturated Compounds. Part I. Esterification of Substituted Acrylic Acids: Dr. J. J. Sudborough and Lorenzo Lloyd.—Formation and Hydrolysis of Esters: Dr. J. J. Sudborough and M. E. Feilmann.—A New Method of Determining Freezing Points of very Dilute Solutions: Dr. M. Wilderman.

FRIDAY, December 17.

Institution of Electrical Engineers (Chemical Society's Rooms), at 8.—Accumulator Traction on Rails and Ordinary Roads: L. Epstein.

Institution of Civil Engineers, at 8.—The Elastic Properties of Steel Wire: Archer D. Keigwin.—The Elasticity of Portland Cement: W. L. Brown.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—By Roadside and River: H. M. Briggs (Stock).—Catalogue of the Books in the Library of the Indian Museum, Supplement 2 (Calcutta).—Memoirs of the Geological Survey, Scotland: The Geology of Cowal: W. Gunn, C. T. Clough, and J. B. Hill (Edinburgh, Neill).—Stirpiculture: Dr. M. L. Holbrook (Fowler).—Studies in Psychical Research: F. Podmore (Paul).—Student's Guide to Submarine Cable Testing: H. K. C. Fisher and J. C. H. Darby (*Electrician* Company).—The Book of the Dead: Dr. E. A. W. Budge, 3 Vols. (Paul).—The Rod in India: H. S. Thomas, 3rd edition (Thacker).—Wild Life in Southern Seas: L. Becke (Unwin).—Famous Problems of Elementary Geometry: Profs. Beman and Smith (Boston, Ginn).—A Text-Book of Special Pathological Anatomy: Prof. E. Ziegler, translated and edited by Drs. D. MacAlister and H. W. Cattell, Sections ix.-xv. (Macmillan).—The Lepidoptera of the British Islands: C. G. Barrett, Vol. 4 (Reeve).—Philip's Revolving Planisphere and Perpetual Calendar (Philip).—Le Végétaux et les Milieux Cosmiques. J. Costantin (Paris, Alcan).

Pamphlets.—Radiography in Marine Zoology: Dr. R. N. Wolfenden (Rebman).—Untersuchung über die Bahn des Cometen 1822 IV.: Dr. A. Stichtenoth (Leipzig, Engelmann).

MENDELÉEFF'S PRINCIPLES OF CHEMISTRY.

The Principles of Chemistry. By D. Mendeléeff. Translated from the Russian (sixth edition) by George Kamensky, A.R.S.M. Edited by T. A. Lawson, B.Sc., Ph.D. Two vols. Pp. xviii + 621 and 518. (London: Longmans, Green, and Co., 1897.)

An English translation of the earlier (fifth) edition of this remarkable book was prepared by Mr. Kamensky, and edited by Mr. A. J. Greenaway, in 1891. It is therefore familiar to the English chemical world; and that a second edition of the English version should be called for in a comparatively short time, is a proof that the views of the author have a fascination which secures for the book a wide circle of readers. The author speaks of it modestly "as an elementary text-book of chemistry"; but it is probable that the previous edition has been exhausted less by a demand on the part of beginners in the subject, for whom, to say truly it is little adapted, than as a consequence of the interest which has been excited among advanced students and professed chemists by the exposition of the doctrine embodied in the so-called "Periodic Law," which is the principal feature of the work. Enough has already been said in the pages of NATURE (see vol. xlv. p. 529) concerning the characteristics of the book itself—the extraordinary development of the foot-notes, which often expand to such dimensions as almost to drive the text out of the page, and which in many cases contain far more interesting matter; the strange inequality in the materials collected, many processes, especially those connected with manufactures, being quite antiquated; and others which need not be recalled. The confusion of proper names, owing to errors of spelling, is not so conspicuous as in the former editions, though one ludicrous substitution occurs in the chapter on spectrum analysis, where Huggins is three times over transformed into Huyghens! Such defects, however, do very little to impair the real value of the book, or obscure the genius of the author. Turning from the attitude of the literary critic to that of the scientific inquirer, it is much more profitable to see what such a chemist as Mendeléeff has to say about special questions of fundamental or primary importance.

In chemistry the word element is in constant use in the sense originally taught by Boyle, that is, signifying something which has up to the present remained undecompounded. At the present day the majority of chemists have probably settled down to the belief that our seventy or eighty "elements" represent limiting material, and that, so far as terrestrial affairs are concerned, so they will always remain. Others—probably however, a minority—conceive that relations among their atomic weights hint that they may be compounded of finer matter united in various ways, and though they may not expect to rupture the bond which unites the subatomic constituents together by any laboratory process, yet they see in the spectral phenomena of the stars evidence that under other conditions this rupture may actually be accomplished. Mendeléeff seems to believe in the permanence of the terrestrial elements, for not only in the two foot-notes on p. 20, vol. i., but in a long digression upon the subject of Prout's hypothesis (p. 439-441, vol. ii.), he emphatically rejects the idea that the atomic weights of other elements have any definite numerical relation to that of hydrogen, and he points out that attempts at transmutation of one element into another have been hitherto fruitless. "All such ideas and hopes," he says, "must now, thanks more especially to Stas, be placed in a region void of any experimental support whatever, and therefore not subject to the discipline of the positive data of science." Now and again, even at the present day, there is a recrudescence of alchemistic pretensions, but it may be noticed that the discovery for which a claim is put forward always relates to the transmutation of a base metal into silver or silver into gold. If any one suggested that he had succeeded, for example, in extracting lead from thallium, he would be laughed at for his pains, but if he boldly asserts that by a long and secret process he has succeeded in making gold out of silver, he generally finds a few people at least ready to take him seriously.

Chemical affinity is another expression still freely used, though with widely different meanings by different chemists; and here again a definite expression of the author's views is fortunately to be found in the pages of his book. He says (p. 27):

> "For a long time, and especially during the first half of this century, chemical attraction and chemical forces were identified with electrical forces. There is certainly an intimate relation between them, for electricity is evolved in chemical reactions, and has also a powerful influence on chemical processes—for instance, compounds are decomposed by the action of an electric current. And the exactly similar relation which exists between chemical phenomena and the phenomena of heat (heat being developed by chemical phenomena, and heat being able to decompose compounds) only proves the unity of the forces of nature, the capability of one force to produce and to be transformed into others. For this reason the identification of chemical force with electricity will not bear experimental proof."

He then goes on in a characteristic foot-note to refer to the facts of substitution or "metalepsy," in which hydrogen, a "positive" element, may be exchanged for chlorine, a "negative" element, without altering the chief chemical characters of the compounds in which the exchange occurs. On a later page, also in a foot-note the author gives an account of the electro-chemical theories of Davy and Berzelius, and their relation to successive hypotheses of the constitution of salts; and here again he seems to reject all modifications of Berzelius' polar doctrine. It must be admitted, however, that the book is not strong in this direction. After much research we have not succeeded in finding a definite statement of such important facts as are embodied in Faraday's laws of electrolysis, the nearest approach to it being found on p. 581, but followed by an apologetic foot-note in which it is stated that the plan and dimensions of the book prevent the author from "entering upon this province of knowledge." This is to be regretted, considering the importance to the chemical student of a good acquaintance with the facts, methods and hypotheses of the now largely-developed province of electro-chemistry.

The preface of the new edition contains a special reference to the author's views concerning solutions—a subject for which he expresses great personal predilection, and to the experimental investigation of which he has devoted some time and labour. A paper by Mendeléeff relating to solutions of alcohol in water was communicated to the Chemical Society of London in 1887. He now states that we have not yet "the right to consider even the most elementary questions respecting solutions as solved." "My own view is that a solution is a homogeneous liquid system of unstable dissociating compounds of the solvent with the substance dissolved." In a foot-note, beginning p. 64, he explains the gas theory as applied to dilute solutions, and expresses the view that the physical and chemical aspects of the question, referring respectively to dilute and strong solutions, must be reconciled. The passage is too long for quotation; but supporters of the so-called hydrate theory may still count the great Russian chemist as on their side, at any rate so far as strong solutions are concerned.

There are, of course, many other subjects which the reader of the book will pursue with much interest, in view of the eminence of the author and the originality with which they are treated; but none of these will equal in attractiveness the subject of the grouping of the elements and the development of the periodic law. It is interesting to remember that, as the author tells us in the preface (p. xii), it was while engaged in writing the first edition of the book in 1869 that he first perceived the scheme and the application of the periodic law in its entirety. But it is only at the opening of the second volume that we come to the exposition of the principles which guided him in the grouping of the elements. This is accompanied by a foot-note which contains a historical *résumé* of the course of events which led ultimately to the recognition of these important principles by all chemists. And here we find a passage (*note* 13, p. 26) which sets forth clearly the depth and solidity of Mendeléeff's conception of the periodic "law," and the superiority of his claim to be regarded as the discoverer of the relation of properties to atomic weight among the elements. Having become convinced that the atomic weights and properties of the elements were mutually related in a certain manner, the Russian chemist did not hesitate to alter accepted atomic weights when required to fall in with the scheme, and to predict the properties of then undiscovered elements; while "neither De Chancourtois, to whom the French ascribe the discovery of the periodic law, nor Newlands, who is put forward by the English, nor L. Meyer, who is now cited by many as its founder, ventured to" do anything of the sort.

As such fortunate and valuable consequences have happily followed the study of the atomic weights by Mendeléeff, it is perhaps hypercritical to complain of his use of the term "law" in the vulgar ambiguous sense.

What after all is a "law of nature"? Is it not a compendium or summary of a series of observed agreements? and the statement so often used by Mendeléeff, that "the laws of nature admit of no exception," by no means proves that exceptions to any and every recognised law of nature may not hereafter be discovered. As such a statement now stands, it merely implies that in most cases the induction is at present incomplete. The question now comes, whether the periodic law itself is a "law of nature"? This is a question which must be troubling very much the discoverer of the law at the present time, now that the individuality of argon and, though less certainly, that of helium have been established. The subject is dealt with in Appendix iii. at the end of the second volume, written by Prof. Mendeléeff in February 1895, and here he clings to the idea that argon is a polymeride of nitrogen, or N_3.

This hypothesis, however, cannot be maintained. All that is known of argon shows that it is a gas having a density lower than 20 ($H = 1$), and hence that its molecular weight is less than 40, while that of N_3 would be 42. Argon and helium can at present be regarded only as a kind of chemical monsters brought unexpected and unwelcome, like the cuckoo, into the previously happy family of the elements where no place is provided for them. What, then, becomes of the "law of nature" if these two substances are admitted to be exceptions to the law as it now stands? and yet that they are exceptions is the conclusion which seems inevitable. W. A. T.

THE NATURAL HISTORY OF THE ANCIENT WORLD.

Les Choses Naturelles dans Homère. Par le Dr. A. Kums. Pp. 194. (Antwerp: Buschmann. Paris: Alcan, 1897.)

Gleanings from the Natural History of the Ancients. By the Rev. M. G. Watkins, M.A. Pp. xiii + 258. (London: Elliot Stock, 1896.)

The Works of Xenophon. Translated by H. G. Dakyns, M.A. Vol. iii. part ii. Pp. lxx + 130. (London: Macmillan and Co., Ltd., 1897.)

Aristotle on Youth and Old Age, Life and Death and Respiration. Translated, with Introduction and Notes, by W. Ogle, M.A., M.D. Pp. 135. (London: Longmans and Co., 1897.)

THE consideration of the animal world is usually approached from one or other of three points of view. We may be interested in the structure—the morphology and physiology—of animals, and in their place in nature: this is the biological interest. Or we may be especially interested in their habits and doings, and every one has at least observed something of the characters and ways of more than one species of animal. Or we may regard animals as objects of the chase or material for human food. The first of these interests is purely scientific; it must exclude hearsay and fancy; it must be based on the most careful observation and examination with the aid of all the appliances that contemporary art and manufacture can furnish; and it must admit nothing that is unverifiable or supported by doubtful authority. On the other hand, the study of the habits and characters of animals can seldom confine itself to lines so rigidly laid down as these; not only is it extremely difficult for the most scientific investigators to interpret or even to record the actions of the lower creatures without a certain, often unconscious, anthropomorphism or reading-in of motives into them; but we are also confronted by a mass of current beliefs and superstitions, and imperfectly authenticated tales which, in view of their frequent repetition and the widespread evidence accorded to them, it is impossible to dismiss unconsidered, improbable though they may seem at first. Such legends can never be wholly banished from view until we have accounted for their coming into being at all; and the naturalist is thus frequently led into the domain of folklore and the study of primitive religious ideas, which from totemistic stages onwards have always in some way or other touched upon the connection of the human and animal worlds. The attitude of the huntsman is different from both those just considered: he makes a very minute study of some of the habits of a few animals, mainly with a view to making himself master of them in a manner gratifying to the sporting instinct.

In the volumes before us all these interests are represented. They all deal with the attitude of the Greeks—in part also of the Romans—to animal nature. Until the time of Aristotle scientific study can hardly be said to have existed, though in him, so far at least as method is concerned, it appears suddenly in almost as systematic a form as any science can boast of at the present day. But hunting and the observation of the ways of animals seem to have been habitual to the Greeks. No one can have failed to notice the unerring accuracy with which Homer, in a few graphic strokes, brings before his readers some familiar scene from nature—the lion and his prey, the jackals surrounding the stag, the tettix, "which in the thickets, sitting on a tree, sendeth forth its thin clear voice," and very many others. Again, the hunting of the boar and of the stag, with all their accompaniments, Homer knew well, and in the works of Dr. Kums and Mr. Watkins all these and kindred topics are treated in some detail. Dr. Kums confines himself to Homer, and it is to students of Homer that his book will be especially interesting. It is an enumeration under classified headings of all that Homer says in different passages about the various departments of nature and human nature, and is a very accurate, complete and well arranged compilation. But it is no disparagement of the book to say that, for the most part, it is not of great general scientific importance. External nature only enters into the poems of Homer as it were by accident, in similes which illustrate human action, or in descriptions of events affecting human agents; and the interest which he arouses is artistic rather than scientific: we are chiefly struck with the perfect description of what the poet saw, with the clearness and truth to life of his pictures. Mr. Watkins, in his "Gleanings," allows himself to range over the whole field of classical literature, and under the title of the "Ancients" he includes not only the Greeks and Romans, but the early Teutonic and Celtic races, and especially our own forefathers; indeed, he deals with much literature that cannot be called "ancient" in the ordinary sense of the word at all, even English literature down to about the sixteenth century. His work is a collection of points which have interested him in the course of his unusually wide reading, in regard to the observation and appreciation of the animal world in periods when science had not become scientific; and we find, not of course a serious or systematic contribution to science or to the history of science, but a delightful mosaic of quotations, anecdotes and folk-lore, very artistically put together, and compared with modern views as expressed in passages from Darwin and other writers. The occasional antiqueness of the author's language, and even the use of the long *s* in the type, which unsympathetic critics would no doubt condemn as affectation, are in keeping with a certain *naiveté* and gracefulness of manner, which add greatly to the pleasure given by the large amount of entertaining information which the book contains. We should not expect in such a book, and we do not find, a complete exposition of the Aristotelian "Systema Naturae"—the only great contribution of the ancient world to natural history and biology; but the author appreciates very fairly indeed the merits of Aristotle and other ancient writers from the naturalist's point of view. Aristotle he recognises as having "sifted much of the popular knowledge, as is his wont"; though even Aristotle is gently censured as uncritical in comparison with modern writers. (To this we shall return.) Pliny, on the other hand,

> "though he lived so much later, was an eager listener to all old women's tales. . . . The vastness of his own compilations, and his perpetual industry in noting any circumstances of interest connected with Natural History, smothered his judgment. He had neither time to sift facts nor to weigh the authority to be attached to the statements of other authors; and these defects leave his great 'Natural History' a *rudis indigestaque moles* which compares unfavourably with the more exact and painstaking work of Aristotle."

It is a pity that Virgil is usually quoted in Dryden's translation (of whose defects Mr. Watkins is himself not unaware); for this rendering hopelessly obscures the quite unique power possessed by Virgil of calling up—often by a single word or line—inimitable pictures of external nature, whether scenery or animal life.

The book contains chapters on dogs, cats, owls, pygmies, elephants, horses, gardens, roses, wolves, fish, oysters and pearls. In a chapter on mythical animals there is a neat discrimination of the causes and characteristics of the animal folk-lore of several early peoples. Homeric and Virgilian natural history receive separate treatment; and a specially interesting portion of the work deals with the Romans as introducers into Britain and acclimatisers of a number of well-known animals and plants. We should like to see a fuller account of the influence on our fauna and flora of the periods marked respectively by the Roman occupation, the influx of monks from the continent, and the return of the Crusaders from the East, to all of which our author believes we can trace the introduction of many species. With the mention of a chapter on "Hunting among the Ancients," we may pass to Mr. Dakyns' translation of the *Cynegeticus* of Xenophon. This is hardly the place for a long notice of this work. Suffice it to say that it contains the same kind of matter as we should expect to find in a volume of the Badminton Library dealing with the same subjects—the hunting and tracking of hares with dogs and nets, and the chase and trapping of deer. The habits of the hare, the training, breeding points and management of dogs, and the functions of the keeper, are very fully treated; incidentally, too, precepts of sporting etiquette are introduced, *e.g.* the following:

> "Here it should be added that the sportsman, who finds himself on cultivated lands should rigidly keep his hands off the fruits of the season, and leave springs and rivers alone. To meddle with them is ugly and base"

(Mr. Dakyns is responsible for this rather odd translation), "not to speak of the bad example of carelessness to the beholder."

The work is a marvellous display of close and intelligent observation by an enthusiastic sportsman, and will be full of interest to persons of similar taste in the present day. Of course it contains a good deal of "keepers' superstition," very similar to the fancies of the modern keeper, but this, perhaps, adds to the interest; and many more or less brilliant suggestions are made in explanation of facts which seemed to be in need of it. Mr. Dakyns' translation is spirited and, on the whole (to judge from passages chosen at random), accurate; and any sportsman into whose hand the book falls will feel grateful to him for rendering accessible the work of, perhaps, the acutest observer of outdoor life in antiquity.

In turning to Dr. Ogle's translation of some of the minor treatises of Aristotle, we enter the domain of science proper. The translator's name is sufficient guarantee of the excellence alike of introduction, translation, and notes: the work is quite up to the standard of the "Parts of Animals" by the same editor. Shortly, the doctrine contained in the treatises translated rests on the belief that life depends upon heat: the source of this heat was the heart, in which heat was continually being generated by the concoction of food received from the stomach and passed into the heart; and the heat thus generated supplied the place of that which was continually being given off by the body. But life might be destroyed by excess no less than by defect of heat; this excess was provided against by respiration, which cooled the violence of the "fire" in the heart, which always tended to become excessive: in the case of pulmonate animals, the air in the lungs was the means of refrigeration; in the case of branchiates, the water playing upon the gills. Natural death (as distinct from death by disease or violence) was due to the gradual exhaustion of vital heat—an idea at least as clearly defined as the "vital force" of many modern physiologists. The causes of longevity (in these and other treatises) are somewhat vaguely stated, but the correlation of longevity with such characters as large size, high organisation and length of the period of gestation, was observed by Aristotle. These points are, of course, worked out in much greater detail, and the exposition of them by Aristotle cannot here be reproduced at length. The first impression of an ordinary reader will probably be that views so absurd and obsolete are not worth consideration. But on further attention, we find that obsolete though these views may be, yet they were the first step towards a really scientific physiology. The physiology of Plato and Democritus was pure guesswork, or at least only guided by preconceived theories not falling within the range of physiology. It was Aristotle who first saw

> "that the study of function must be preceded by the study of structure, or in other words, that physiology must be based upon anatomy. . . . By insisting on the absolute necessity of anatomical observation, he carried biology at one step from the world of dreams into the world of realities; he set the science on a substantial basis, and may indeed be said to have been its founder, for the same imaginings of his predecessors can hardly be dignified with the name of science."

And, to quote a later passage of Dr. Ogle's introduction:

> "If we perform the difficult task of excluding from our minds all ideas and facts since acquired, we shall find ourselves constrained to admit that in Aristotle's days no better hypothesis could have been devised with which to colligate the facts or supposed facts then available."

And when we consider that such ideas and facts include among others those of chemical combination, the circulation of the blood and the existence of nerves, we shall be surprised to find the difference between the Aristotelian and the modern theories so slight as it is. In fact, as Dr. Ogle shows both in the introduction and notes, a very slight alteration of terminology is often all that is required to convert Aristotle's statements into propositions which would still be accepted as true; and even in their crude form, many of his doctrines (or something very like them) were held by the most advanced scientific men of recent centuries, Harvey himself among others. It is further remarkable that Aristotle should, with the extremely inadequate instruments and appliances at his command, have produced results so accurate in the region of anatomy and embryology: his account, *e.g.* of the lung, is a model of careful description so far as it goes, and the work before us will provide many other instances. Aristotle, of course, had his defects, and his editor points these out frankly: he occasionally (though far less than any other ancient author) took mere hearsay for fact; and he was scarcely alive to the importance of experiment. But he had a definite method of investigation; his conclusions were always based on recorded observations of himself and others; the advance he made was almost incredibly great for one man; and the lines he laid down have been (though unconsciously) followed and developed by all great physiologists ever since. To quote Dr. Ogle once more:

> "There are minds to which the mistakes and shortcomings of great men apparently present greater attraction than their achievements. To them Bacon is but a man who believed in the spontaneous generation of mistletoe; Cuvier, an upholder of the fixity of species; Kepler, one who thought that the huge volcanoes in the moon were artificial structures built by its inhabitants; Descartes, an asserter of the immediate transmission of light; and Newton himself an advocate of the emission theory. To such persons Aristotle's anatomical statements will doubtless supply much desirable pabulum. But those more genial critics who prefer to dwell upon what a man has done well rather than what he has left undone or done amiss . . . will admit that never has a science been started on its career by its originator with so large an equipment of facts and ideas as that with which Comparative Anatomy left the hands of Aristotle."

THE MEASUREMENT OF RAPIDLY VARYING ELECTRIC PRESSURE.

The Capillary Electrometer: its Theory and Practice. Part i. By G. J. Burch, M.A. Pp. 54. Reprinted from the *Electrician.* (London: G. Tucker.)

MUCH of the present knowledge concerning the capillary electrometer is due to the author of this little book. The instrument was invented in 1875 by Prof. Lippmann, but for twenty years it was hardly used by any people except physiologists, and even by them only in a doubtful sort of way, for they thought that its indication gave merely the period and direction of a sudden change of P.D., and they feared that the magnitude of the variation could not be deduced from the excursion of the meniscus formed at the junction of the threads of mercury and dilute sulphuric acid.

It may be well to mention that we use the letters "P.D.," not merely because they appear to us to be a convenient abbreviation for "potential-difference," but because Mr. Burch, by employing them throughout his book, shows that he has the same opinion.

The book commences with a description of the best methods of constructing a capillary electrometer to which the author's experience has led him, and the reader is warned regarding the faults which he is likely to meet with in the practical use of the instrument, and instructed how to overcome those that can be remedied without making a new instrument.

The first two points that Mr. Burch determined to ascertain experimentally, when he began his work on the capillary electrometer in 1886, were: (1) Does any current pass through the instrument after the meniscus in the capillary tube has reached its stable position for the particular P.D. applied; and (2) does any leakage take place through the instrument if the applied P.D. be withdrawn after the meniscus has been deflected? To each of these questions experiment gave a negative answer, and he was, therefore, led to the conclusion that, although the circuit of a capillary electrometer is composed entirely of conducting substances, and, although there is no visible insulating dielectric, the instrument transmits no current with a P.D. of less than 0·5 volt, but merely receives and maintains a charge as if it were a well-insulated condenser.

The capacity of different capillary electrometers was found by the author to vary between 0·1 and 30 microfarads, but instruments having a capacity of between 0·5 and 2 microfarads gave the best results. When the capacity is unchanged on moving the mercury thread through a considerable portion of the capillary tube the electrometer is found to be equally sensitive throughout that part of the tube.

The author concludes that this instrument is essentially adapted to the poor man, since its cost, including that of the microscope, is less than that of any other electrometer of the same sensibility. It also has the advantage of responding with extreme rapidity to every change of potential.

Various methods are described in detail for obtaining records on photographic plates, having a rapid linear or circular motion, and the author shows how the instantaneous value of a rapidly varying P.D. can be deduced at any point of the photographic curve from the fact, which he proves, viz. that the value of the applied P.D. is measured at any moment by the instantaneous distance of the meniscus from the zero position *plus* the rate of motion of the meniscus at that moment. And in the case of the photographic plate moving circularly, he points out that the second term, depending on the instantaneous value of the velocity of the meniscus, is given by the length of the subnormal to the curve at the particular point.

The book concludes with some interesting examples of curves obtained with telephones, direct and alternate current dynamos, &c., from which the value of the capillary electrometer may be clearly seen.

The reasoning in some parts of the book is not very clear; and, while the figures of the parts of the apparatus itself are in many cases bold and well executed, those illustrating the geometrical reasoning, and the results obtained with the photographic plates, are not as intelligible as one would like. We hope to see Part ii. of this book at an early date; and, for the benefit of those who do not resemble the author in being masters in the use and the theory of the capillary electrometer, we trust that he will not hesitate to sacrifice compression to clearness.

W. E. A.

OUR BOOK SHELF.

A Handbook to the Geology of Cambridgeshire, for the Use of Students. By F. R. Cowper Reed, M.A., F.G.S. 8vo. Pp. x2 + 76. (Cambridge: at the University Press, 1897.)

THE geology of Cambridgeshire possesses a special interest for many students. From Cambridge itself there have sprung a greater number of expert British geologists than from any other seat of learning in this country. Though founded by John Woodward, the school was created by Sedgwick; and it has been carried on with signal success by Prof. Hughes. This success, as the present Professor has cordially acknowledged, is partly due to the band of brilliant assistants he has gathered around him. Thus special instruction is given in all branches of geology, and the author of the present work has during recent years rendered aid in the department of stratigraphical palæontology. To a casual visitor the scenery and geology of Cambridgeshire may offer but few attractions, for the country is mostly low-lying, and there is much clay-land and fen. Oxford affords a greater variety of scenery and a more attractive series of fossiliferous formations. Nevertheless, there is much in Cambridgeshire geology to arouse interest when once an enthusiasm for the science has been kindled, and there was need of a concise handbook which should clearly describe and explain the leading facts that have been made known. The excellent "Sketch" by Prof. Bonney dates back to 1875, and the more detailed geological survey memoir on the neighbourhood of Cambridge, by Penning and Jukes-Browne, was issued in 1881. The present work is a model of what a county geology should be. The zones in the Jurassic and Cretaceous rocks, the phosphatic nodules in Lower Greensand and Chalk, the glacial deposits, valley-drifts, and recent accumulations, are all duly described and accompanied by full records of the fossils. If we find fault at all, it is that the author has entered at too great a length into certain contrary views regarding the formation of the Chalky Boulder Clay, for the extraordinary "diluvial theory," as he himself admits, "finds few supporters at the present time." Even the view of S. V. Wood, jun. (noted on p. 168), was modified in that geologist's latest publication.

Our author rightly wanders a little out of the county to give some account of the Red Chalk of Hunstanton, because it is so frequently visited by Cambridge students.

Brief chapters are given on the antiquity of man and on water supply. With regard to the latter subject, we would question the statement (quoted by the author) that "if the Oxford Clay was pierced we might reasonably expect an abundant supply of water." The outcrop of Lower Oolites is some distance away, while at St.

Neots the water that was obtained at a depth below the surface was saline in character. A full and useful bibliography completes this excellent and well-arranged work.
H. B. W.

Wild Traits in Tame Animals. By Louis Robinson, M.D. Pp. vii + 329. Illustrated. (Edinburgh and London: Blackwood and Sons, 1897.)

Dr. Robinson points out in his introduction that the amateur naturalist is a valuable and necessary member of the scientific community. He detects a tendency on the part of the professional naturalist to warn the amateur off the ground. Whether any such mischievous claim of proprietorship is actually set up is not clear to us; the naturalist who pursues his hobby for recreation only is, according to our own experience, welcomed by everybody, if only he is a good fellow, who will bring in his own contributions, great or small, to the general stock, and not spread false information. Dr. Robinson's animated defence of the amateur naturalist may therefore be gladly allowed to prevail; we are only surprised to learn that any defence is needed.

Our author holds that no one in these days can study animals with due profit who is not a Darwinian; he would have his amateur naturalist "an evolutionist down to the tips of his toes." We are not so heartily on his side here. There is risk of spoiling a quick and trustworthy observer by saturating his mind with theories. If natural facts are reported to us, they do not gain in credibility by being expressed in evolutionary phrase. It is good that every naturalist should think upon his facts, but let him think independently, not as an evolutionist, nor as a partisan of any school whatever.

We like the papers which form the bulk of the book much better than the introduction. Dr. Robinson discourses upon dogs, horses, donkeys, cattle, sheep, goats, pigs, cats and poultry. The first two of these seem to us the most interesting, but all possess good points. The author gives us a lively object-lesson upon each animal, trying to explain its structure and habits by the mode of life of its wild progenitors. Very many of his interpretations have been anticipated; that is to be expected; but everything is cast into a new and engaging form; it reads like personal experiences illuminated by the writer's own reflections. No reader who thinks for himself will accept all Dr. Robinson's conclusions, but he will find his interest in the subject heightened, and his sagacity exercised by these amusing dissertations.
L. C. M.

The Psychology of the Emotions. By Th. Ribot. Pp. xix + 455. (London: Walter Scott, Ltd., 1897.)

In this book Prof. Ribot gives a very complete account of his subject. In the first part he deals with pleasure and pain and the general nature of emotion. He advocates a theory of emotion which he terms "physiological." Feeling is regarded as a primary aspect of mental life, closely connected with biological conditions; and the author seems to think that it is hopeless in this region of psychology, at any rate, to depend wholly on purely psychological methods, the subject only becoming intelligible by going beyond consciousness and treating it in its physiological relations. As part of this general theory Prof. Ribot adopts, with some qualification, the theory illustrated by James in the words, "we feel sorry because we cry, angry because we strike, afraid because we tremble." In the second part, dealing with the special forms of emotion, no attempt is made to give an elaborate classification; but the chief aspects of emotional life are described in the order in which they seem to have developed. In this part, and especially in the chapters on character and temperament, the author brings out the great value of pathology in the study of psychology.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The Passive Condition of Resting Protoplasts.

The appearance in your last issue of a short paper recently communicated to the Royal Society by myself and Mr. F. Escombe, on the "Influence of very Low Temperatures on the Germinative Power of Seeds," affords me an opportunity of calling attention to two important papers which only became known to us after our own was in print. Both these communications materially strengthen the argument against the necessary existence in resting protoplasts of ordinary respiratory exchanges, or of any metabolic changes resulting in "intra-molecular respiration."

The first paper is by W. Kochs (*Biol. Centralbl.*, 10 (1890), 673), who has shown that dry seeds, placed for many months in the vacuum of a Geissler's tube, do not evolve an amount of carbon dioxide or nitrogen capable of detection by subsequent spectroscopic examination of the contents of the tube, a fact which certainly negatives the idea of any gaseous evolution by "intra-molecular respiration."

The other omission is one which is much less excusable, since it has reference to a very important letter communicated to your columns by Prof. Giglioli as recently as October 3, 1895.

In continuation of certain experiments, described in 1878, on the power of resistance of seeds of *Medicago sativa* to the action of certain gaseous and liquid chemical reagents, Prof. Giglioli re-examined the seeds which had been placed under these special conditions continuously for a period of more than *sixteen years.* He found that some of the seeds retained their vitality even when surrounded by atmospheres of nitrogen, chlorine, hydrogen, arseniuretted hydrogen, and nitric oxide; whilst immersion for sixteen years in strong alcohol, and in an alcoholic solution of mercuric chloride, still left a large number of seeds capable of subsequent germination.

That we have been anticipated in some of the conclusions of our paper, based on a totally different method of experiment, will be clearly seen from the following quotations from Prof. Giglioli's letter:—

"My experiments encourage, moreover, the suspicion that latent vitality may last indefinitely when sufficient care is taken to prevent all exchange with the surrounding medium." . . . "It is a common notion that life, or capacity for life, is always connected with continuous chemical and physical change. The very existence of living matter is supposed to imply change. There is now reason for believing that living matter may exist, in a completely passive state, without any chemical change whatever, and may therefore maintain its special properties for an indefinite time, as is the case with mineral and all lifeless matter. Chemical change in living matter means active life, the wear and tear of which necessarily leads to death. Latent life, when completely passive, in a chemical sense, ought to be life without death."

Prof. Giglioli concludes his letter with a reference to the possibility of an extra-terrestrial origin of life on the earth, through the medium of meteorites.
Horace T. Brown.

52 Nevern Square, Kensington, December 13.

Discovery of a Large Supply of "Natural Gas" at Waldron, Sussex.

The discovery of this gas occurred accidentally while boring for water in the parish of Waldron, Sussex. The boring was commenced in the lower strata of the "Ashdown sand" (Hastings beds), and was continued to the depth of 377 feet, when the work was stopped. A strong smell of "gas" having been noticed, a light was applied to the top of the lining tube of the bore, and a flame immediately sprang up to the height of 15 or 16 feet, and burned with great fury until it was put out by means of damped cloths being thrown on to the top of the tube (Fig. 1).

It is not quite certain at what level the first release of the gas occurred; and the workmen say that they noticed the smell of it for nearly a month before the testing with a light occurred, during which time boring was carried on.

An iron cap has now been fixed on the top of the tube with a vent. allowing an escape of the gas to take place continuously (see Fig. 2). When lighted this jet flares out about the same size and colour as one of the "naphtha flarers" commonly used for lighting at fairs and markets, viz. about 12-inch flame. This cap and vent have now already been fixed about fifteen months, and the gas from the vent can be lit at any time, and shows no sign of diminution

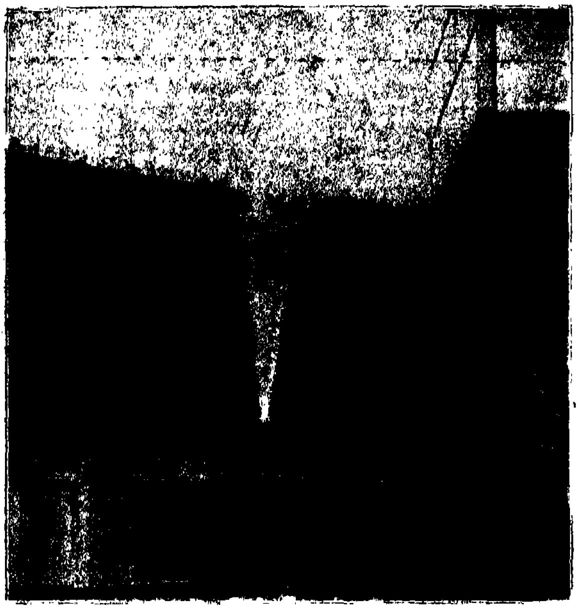

Fig. 1.—Flame of natural gas from bore-hole at Waldron, before the present cap was fixed on the tube. The broken line near the top shows the height of the flame through the six-inch bore-tube.

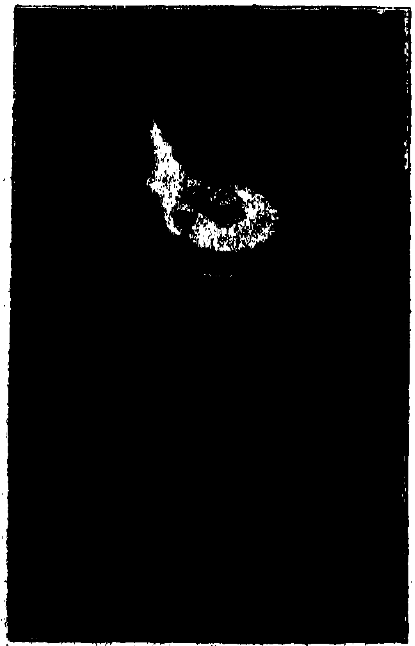

Fig. 2.—Bore-tube in well, with cap having a small vent fixed upon the top. The flame of natural gas is shown rising to the left.

I have taken samples of the gas, and submitted it to the county analyst for East Sussex (Mr. S. A. Woodhead), and he informs me, although he has not yet completed his analysis, that the gas is probably derived from petroleum. The presence of certain beds impregnated with petroleum underlying these Wealden beds in East Sussex, has been noticed before while making deep shafts and borings.

Many of the beds in the Purbeck strata (Brightling series) consist of dark leathery shales which emit a strong odour of petroleum, and small traces of it are also occasionally met with in the Gypsum quarries at Netherfield (Sussex). Beds of lignite, and a variety resembling "Cannel coal" (about 2 feet thick) have been met with near the surface in the parish of Waldron (Lower bed of Ashdown sand, Fairlight clays), and several bands of lignite were pierced by the boring at Waldron where the "gas" was found.

The gas is probably derived from these beds of lignite, and perhaps from the petroleum shales of the Purbeck beds; or possibly, but less probably, from the Kimeridge clay underlying these beds (Sub-Wealden boring), which contains a hard, light-coloured bed rich in petroleum.

In reading through the quarterly reports of Mr. Henry Willett, made during the progress of the Sub-Wealden boring (Netherfield, 1875), I find that strange oscillations had been noticed in the depth of the water in the bore-tube. These were attributed to the "accumulation and discharge of carbonic acid, and of inflammable gases derived probably from the petroleum-bearing strata beneath. The discharge of these gases was proved by the extinction of light at various depths, and by an *explosion* at another time."

The discovery of the gas has hitherto been kept a secret among a few. There appears to be at present an ample supply of gas for the lighting of a town if the necessary plant were erected in connection with the tube, and there also seems to be, so far as one can judge, a constant supply. How long it may continue is, of course, a matter of conjecture; but having already run to waste so long without any decrease in force, I think that the supply might be made use of with reasonable prospects of lengthy continuance.

This notice must be regarded as a preliminary one merely, as I am making experiments with the gas, and examining the cores of the boring with a view to ascertain the source of the supply.

Charles Dawson.

Uckfield, Sussex.

THE ORIENTATION OF GREEK TEMPLES.[1]

In giving an account of my second series of observations on the orientations of Greek temples, and the chronological deductions which may be made from them, it seems desirable to recapitulate as briefly as possible the main points which underlie the inquiry.

The subject was introduced to me about eight years ago by Sir Norman Lockyer, who had discovered that there was a very strong probability that in every case the axis of an Egyptian temple, or in other words its orientation, was aligned to that point of the local horizon where at the time of its foundation some conspicuous star rose or set, and that in the case of temples oriented within zodiacal limits, it was also so arranged that on the day of the principal feast of any particular temple, which always took place on a day when the sun at its rising would shine upon the altar or statue of the god, the star should be seen from the sanctuary, through the always narrow eastern opening, shortly before sunrise.

There is plenty of evidence from various sources that *heliacal* stars, as they are called; that is, stars when just visible at their rising before their light is overpowered by the rays of the rising sun, or setting whilst still distinguishable, were very much observed by the ancients. And the use of an heliacal star so observed in connection with temple worship was to give warning to the priests to enable them to be ready for the sacrifice or other function at the exact moment of sunrise. Roughly speaking, a bright heliacal star would in Greece give nearly an hour's warning of the sun's approach, though somewhat less in Egypt.

If in almost every case a connection, such as I have indicated, between the *orientation* of a *temple* and the sunrise effect in the sanctuary, preceded by an heliacal star, can be established, it carries an amount of probability of the truth of the theory which it is very hard to gainsay.

---

[1] Abstract of a paper read before the Royal Society, March 11, 1897. On the Orientation of certain Greek Temples, and the Dates of their Foundation, derived from Astronomical Considerations—being a supplement to a paper on the same subject published in the *Transactions* of the Royal Society in 1893—by F. C. Penrose, F.R.S

To us the practical use of such theory is, that it gives the means of determining very approximately the date of the foundation of any temple, namely the time when the sunrise and the heliacal star were so connected.

As seen from a given point at its rising or setting, the amplitude of a star (that is, its bearing from true east or west) is subject, as time goes on, to a slow alteration resulting from the displacement of the star, in consequence of the celestial movement called the precession of the equinoxes, and this can be calculated with great precision so as to show the date at which it would have been visible as the forerunner of the sun from the sanctuary of a temple. There is architectural evidence in Egypt that attempts had been made to retain the use of such stars, and in two ways: one by a structural alteration in the eastern opening, so as still to allow of its being seen; and the other as evidenced by finding that a temple, architecturally of later date, but of the same cult, had been built alongside of an older temple which had lost the star which had at one time served as its morning clock.

Sir Norman Lockyer having been satisfied that the principles of temple building, as above mentioned, had prevailed in Egypt, and being led by a cursory examination of Greek examples to suspect that the same would be found to prevail in that country also, invited me to take up this inquiry with respect to Greek temples, which led to my making a preliminary communication to the Society of Antiquaries in 1891, and a more detailed report to the Royal Society in 1893, of which an abstract appeared in NATURE, May 11, of that year. The paper itself was published in the *Transactions* of the Royal Society (vol. 184, pp. 805 *et sqq.*) to which the supplement, already referred to, was published in vol. 190, pp. 43 *et sqq.* The first series contains more than thirty examples, the second nearly as many, and both collections entirely confirm the view of the matter already made highly probable from Egyptian sources. Indeed the second series, chiefly drawn from colonial Greece, is in one respect more satisfactory than the previous one.

The architectural remains of the greater number of the temples in Greece proper, comprised in the first list, do not accord with the early dates derived by calculation from their orientations; and it is necessary to assume that in the majority of cases a temple, of which we find the ruins, was built parallel to the lines of an earlier structure which had conformed to the orientation postulate, and the date arrived at is that of the first foundation on the site. Traces of such earlier foundation can, however, be actually found or inferred in a sufficiently large proportion of the whole to justify the assumption; but in more than half the cases they have either disappeared or not yet been found. In the colonial examples of the last series, however, quite two-thirds of the orientation dates are consistent with the architectural remains now standing, without need of any hypothesis respecting foundations as yet undiscovered.

All the temples I have met with in Magna Grecia or Sicily are what may be named solar temples; namely, those which admit of being lighted through an eastern door by the sun when rising in the line of the axis. Three of them, indeed, lie on the solstitial limits; of this I did not find any examples in Greece. The nature of the inquiry in a solar temple is of this kind, viz.: given the angle of orientation, and the apparent height of the eastern horizon, we calculate the declination which the sun would have required to illuminate the sanctuary at its rising (allowance being made for the variation of the obliquity of the ecliptic many years ago, an allowance which may require a small correction when an approximate date has been arrived at). From this the sun's right ascension is computed, giving generally two values—one vernal, the other autumnal. The next search is made for a suitable star. It must be remembered that in the case of a rising star the declination cannot differ much from that of the sun, or else it could not be seen through the same narrow opening, and to be serviceable as a warning star, it must precede in right ascension by a suitable interval; if too short the star could not be seen, if too long its warning would be inconveniently early. Thus the data for the preliminary search are: for declination, that already ascertained for the sun, and for right ascension, one hour less may be taken.

It would occupy too much space to enter into the details of the calculation which involves the change due to the movement of the star from *precession*; but if the result shows that a conspicuous star or constellation, either in the spring or autumn (and within the limits of possible archæology), occupied approximately the position required by the hypothesis, the discovery will justify a more exact computation. Should it, however, fail for a rising star, there still remains the search for a setting star which would fulfil the proper conditions. The search is conducted on analogous principles, but with difference in detail.

In more than fifty cases which I have tried by the four lines of investigation indicated above, I have succeeded in finding in each one solution, and one only. In two I have obtained an alternative possible star; the choice between the two requiring to be settled archæologically. In not one case of which I had full particulars have I failed to find an answer.

An objection has been made that, as there are so many stars in the heavens, some solution of the problem is inevitable, without there having originally been any intentional correspondence. The answer is not difficult.

Firstly, there are very few available stars. They must be of sufficient brightness: a third magnitude star is the very minimum, and could only be resorted to (unless in a close constellation like the Pleïades or Aquarius) if situated very much by itself, so as not to be mistaken for any other. They must also be near enough to the ecliptic to be seen through the narrow eastern opening. A list of fourteen single stars and two star groups exhausts the whole possible number. Moreover, they must be so placed in the firmament as to satisfy the condition required for warning stars. Again, in the two hundred trials made for the fifty temples, as mentioned above, would there (in the case of the assumed multitude of stars) have been one hundred and fifty misses to the fifty hits which were wanted; and if there had been no arrangement, and the orientations had been fortuitous, would the most ancient sites have always secured the oldest orientation dates, and those of which the recent foundation is historically known have taken their proper rank?

It is true that the sequence might have been acceptable, but not so the exactness of the dates. These must depend upon the correctness of certain assumptions with regard to the elements of the problem, especially as to the altitude of the star and the depression of the sun at the heliacal phase, if it may be so called.

From a good deal of attention which I paid to the visibility of stars in twilight I derived the following rules, from which all the calculations have been made, except in a very few cases where local circumstances required some modification. The rules are made for the case of rising stars. When setting in the morning twilight they may be seen nearer to actual sunrise; but it is probable that the same rule would have been applied, as the same time would have been required for warning, whether a rising or setting star was used. It may be observed that rising stars seem to have been the favourites, in proportion of about three to two.

In ordinary fair weather in Greece or in South Italy I found that a first magnitude star can be seen at an altitude of 3° when the sun is 10° below the true horizon. A second magnitude should require an altitude of 3° 30′, with the sun depressed 11°; whilst a third magnitude star, of the use of which there are very few examples, would require a depression of 13°. A general confirmation of these elements may be drawn from Biot's "Recherches sur l'Année Vague des Égyptiens," in which he derives from Ptolemy that in Egypt a solar depression of 11° was considered proper for the observation of heliacal stars. This seems a very reasonable mean for the rules of solar depression applying to stars of different magnitudes as given above.

Following these rules, I obtained orientation dates for the temples I examined last year as below.

—	—	—	Orientation date	—	—
			B. C.		
	Athens	A small temple near Jupiter Olympius ...	780	September 23	Spica setting
	,, ...	The ancient Asclepieium	560	April 5 ...	α Arietis rising
Greece ...	Delphi	First foundation of Temple of Apollo ...	970	March 1 ...	β Lupi setting
	,, ...	Rebuilt so as to follow the star	630		,, ,,
	Argos	The ancient Heræum	1830	October 24 ...	Antares rising
	Taranto	A Doric Temple	640	November 10	,, ,,
	Metapontum ...	Foundations of a temple near San Sansoni...	610	December 21	β Geminorum setting
Calabria ...	,, ...	Doric Temple	580	March 6 ...	γ Pegasi rising
	Near Cotrone ...	Temple of Juno Lacinia on Cape Colonna ...	1000	March 28 ...	α Arietis rising
	Near Gerace ...	Ionic Temple of the Locrians	610	December 21	β Geminorum rising
	,, ,, ...	Ditto rebuilt on same site	430	November 23	β Tauri setting
	Girgenti	Temple of (attributed to) Juno Lacinia ...	690	April 1 ...	α Arietis rising
	,, ...	,, ,, Hercules	470	March 20 ...	Spica setting
Sicily ...	,, ...	,, ,, Concord	450	,, ...	,, ,,
	,, ...	,, ,, Jupiter	430	April 14 ...	α Arietis rising
	,, ...	,, ,, Castor	400	September 13	Spica setting
	Segeste	Temple (perhaps) of Jupiter	550	April 5 ...	α Arietis rising
	Selinus	The Archaic Temple called Temple C ...	795	September 30	α Arietis setting
	,, ...	Temple D (adjoining and following the star)	610	October 4 ...	,, ,,
	,, ...	Temple A	550	March 5 ...	γ Pegasi rising
	Syracuse	Temple forming part of Duomo	815	September 20	Spica rising
	,, ...	,, of Jupiter	610	October 3 ...	α Arietis setting
	,, ...	,, ,, Diana	450	September 26	Spica rising
	Pœstum	,, ,, Neptune	535	March 22 ...	Spica setting
South Italy..	Pompeii	Doric Temple in triangular Forum	640	November 12	Antares rising
	,, ...	Temple of Isis	750	June 19 ...	β Geminorum rising

For the sake of comparing the above with dates that are archæologically probable, and confining the inquiry to the Greek colonies, we may observe:

The Doric capital at Taranto is of an extremely ponderous type, and may well be assigned to the seventh century. A Lacedemonian colony under Phalanthus is reported to have taken possession of Tarentum about 700 B.C.

At Metapontum, at the temple near San Sansoni, nothing but foundations remain; the architectural character of the other is quite in accordance with the orientation date. The city was one of the most ancient in South Italy. One column only remains of the temple on Cape Colonna near Cotrone, and its character is that of the fifth century. In the case of this celebrated temple we clearly have the case of a rebuilding on the old lines.

The foundations of the older temple of the Locrians near Gerace were discovered under the substructions of the later temple. Its orientation date, 610, is quite consistent both with the early Ionic architecture which was found, and that of the Hellenic colonisation, 683 B.C. That of the later temple is also in accordance with the architecture of the fifth century. Girgenti was occupied by a Greek colony B.C. 582, but a city with so commanding a site had, no doubt, an earlier foundation; and we may feel confident that the temple of Juno Lacinia, though the present structure is Hellenic, was founded by the earlier inhabitants. The remains of the other temples agree in style with the dates assigned to them by the theory. Mention is made by Diodorus of the temple of Jupiter strongly confirmatory of the orientation date 430 B.C. At Segesta the date arrived at is too early by about 100 years to agree with the character of the architecture. It may have been that the Segestans, who seem always to have been a struggling community, may have taken a very long time to have brought their temple to the state of finish at which at last it arrived, for it appears never to have been quite completed.

Selinus offers the example of one temple—a temple remarkable for the archaic character both of its masonry and its sculpture—of which the orientation date anticipates the arrival of the Hellenic colony which occupied the place in 628 B.C., but in the other examples in that city the orientation dates are quite consistent both with the architecture and with Hellenic citizenship. Syracuse was colonised in 734 B.C. The orientation date of the "Duomo" temple is eighty years too early for agreement with that epoch. The architecture is indeed very rude, but perhaps some small variation in the elements of the calculation should be made, which would bring it within the Hellenic period. The dates of the other two temples at Syracuse are extremely probable. The date, 535 B.C., assigned to the Temple of Neptune at Pœstum, appears to be thoroughly suitable to its massive but advanced style, and is confirmed by a passage in Herodotus, in which, although he does not make any allusion to the temple, yet speaks of a Posidonian architect of great celebrity at that very date. The temple of Isis at Pompeii is remarkable from there being evidence of a large window having been formed in the temenos wall centrally placed with regard to the eastern axis of the temple, doubtless for the admission of the rising sun and its warning star. The window had been filled up with brickwork at some subsequent date. The last point touched upon in the paper has reference to a group of ten temples of late foundation, of most of which the dates are accurately known. At first these temples seemed to be exceptions to the rules which connect the orientation with heliacal stars, but by allowing a few more degrees of solar depression than what is absolutely necessary for distinct vision, they are found to conform in all other respects. The explanation of this change seems to be that the temple service had become more complicated, and more time was required by the priests for their preparations. Every additional degree of sun depression would add about five minutes for that purpose. The maximum extra allowance in this group of temples is thirty-five minutes."

F. C. PENROSE.

NATURE AND A CAMERA.[1]

THE remarkably favourable reception accorded by the public and the press to the earlier effort of the Messrs. Kearton has naturally tempted them to another venture; and the volume before us shows no falling off in the matter of interest and the exquisite execution of the illustrations from its predecessor. Only too frequently authors, having scored one success, are apt to think their hold on the public will permit of a very inferior second effort obtaining the same share of patronage as the first, and any odd scraps of new information they may possess are, with the aid of abundant "padding," worked up to form a volume of the required dimensions. The present work displays in an equally marked degree the freshness and brightness so conspicuous in "British Birds' Nests"; and as covering a wider area is calculated to attract an even larger circle of readers. One of the best tests of a work of this nature is its capability of arousing the interest of young persons, and this, from practical experience, we find to be the case with the volume before us.

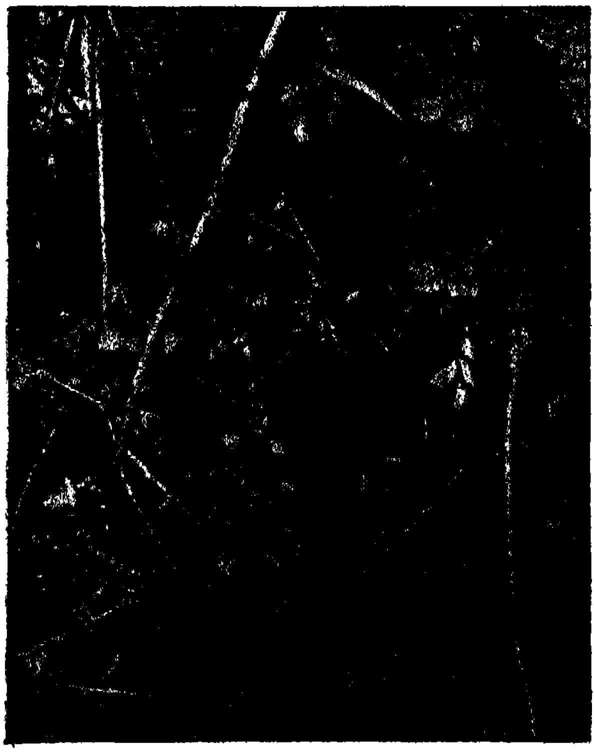

FIG. 1.—Nightingale on Nest. (From "With Nature and a Camera.")

Photography in the hands of artists of the capacity and perseverance of Mr. Cherry Kearton is undoubtedly the only real method of portraying animals in their native haunts, and more especially birds on their nests; and in the truthful representations of objects of the latter class the present volume can fear few rivals. Nothing can be more exquisite than the illustration of a nightingale on her nest, which the publishers have permitted us to reproduce (Fig. 1); but this is only one among many of the same excellence and interest, those of the whitethroat and the chiffchaff being, if possible, even more beautiful. The only thing we miss in illustrations of this nature is colour, which would be of especial value in photographs, like the upper one on page 253, dealing with the protective resemblances of animals to their surroundings. Possibly even this want may be supplied in the near future.

But it is by no means the beauty of the illustrations alone that calls for commendation in the work; many of the observations in the text claim recognition from all interested in the habits of British animals, while some have a bearing on considerations of a higher nature. For instance, in regard to protective resemblance, Mr. Kearton says he is puzzled by the circumstance that while young terns instinctively recognise its value, some of their parents apparently do not and others do. This is exemplified as follows: "As a rule, Sandwich terns' eggs harmonise closely with their surroundings, and even the experienced field naturalist has to exercise a great deal of care to avoid treading upon a clutch when visiting a breeding station. A friend of mine told me a few years back that he had once visited a colony of these birds on an island where the natural breeding accommodation was so limited that many of them had conveyed patches of pebbles on to the grass, and laid their eggs thereon. We both recognised this as a wonderful instance of the knowledge of the value of protective coloration; but I must confess that last summer at the Farne Islands my faith in the wisdom of these birds received a rude shock when I met with five or six clutches of eggs lying most conspicuously on small circular patches of broken mussel-shells, the dark blue of which contrasted violently with the golden grey of the sand." From this it would almost seem that the birds are unable to distinguish between a mussel-shell and a pebble, and that any cluster of small smooth objects looks to them equally suitable as a nesting site.

Although the greater portion of the work is devoted to birds in their haunts, the subjects treated of are diverse. To the general reader and tourist the chapters on the people and birds of St. Kilda will, perhaps, be the most interesting; while the sportsman will find much to attract him in those on gamekeepers and duck-decoying. To the amateur photographer the volume will appeal not only as a standard of excellence at which to aim as regards his own efforts, but more especially from the account given in the final chapter of Mr. Kearton's method of photographing. From this latter it will be apparent that the task of portraying many kinds of birds—especially when they inhabit lakes or beetling sea-cliffs—in their native haunts, is no easy one, but rather one beset with numerous dangers to life and limb. In the preface the author deprecates the charge of foolhardiness, and the results obtained go far to justify the risks necessarily incurred.

In the chapter on sea-birds and their haunts will be found some of the matter most interesting to the ornithologist, and it is here that some of the most successful of the photographs occur. As an example, we select, partly on account of its small size, the figure of a solitary razorbill mounting guard over its egg reposing lower down on the side of a pinnacle of rock (Fig. 2). But for beauty of detail and execution we may refer to the gull's nest with egg and young, and the group of puffins on p. 269, and also to the nest of the black-headed gull on the following page. To obtain the photograph of gannets nesting on the Bass Rock, Mr. Cherry Kearton ran risks which evoked the fear of even the adventurous natives of the district. When once their haunts are gained, gannets with young are however, according to our author, very easy birds to photograph, as they will permit the observer to walk among them with no more protest than an occasional peck at his legs. Much has of late years been written on the destruction by human agency of our sea-birds; and it is, therefore, of interest to note that other causes likewise aid to no inconsiderable extent in the diminution of their numbers. "The mortality among sea-birds of all kinds," writes our author, "reckoning the loss of eggs and young ones, from purely natural causes alone, must be very great in the course of a season. We saw a great number of young terns lying dead everywhere upon these islands, and Watcher Darling told us that two years ago very few Arctic or common terns got away. He picked up several dead ones with sand-eels in their bills, and concluded that there was no small fry for them, and that the eels, although the natural diet of Sandwich terns, were too large for the young of the smaller species to swallow."

---

[1] "With Nature and a Camera, being the Adventures and Observations of a Field-Naturalist and an Animal Photographer." By R. Kearton, with Photographs by C. Kearton. 8vo. Pp. xvi + 368, illustrated. (London: Cassell and Co., Ltd., 1897.)

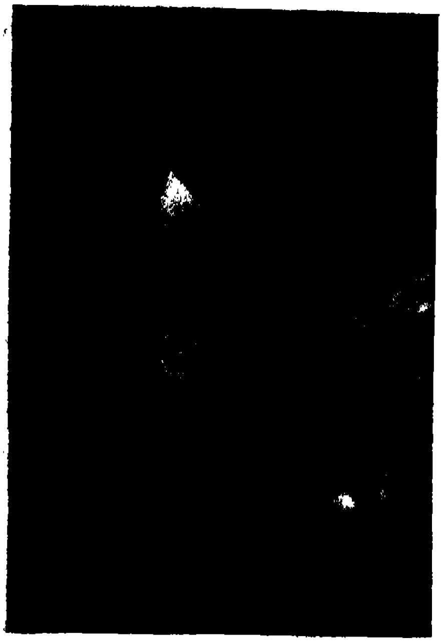

FIG. 2.—Razorbill and Egg. (From "With Nature and a Camera.")

Most of us suppose that the eider is pre-eminent for the quantity of down she employs for lining her nest; but in this, according to our author, she is beaten by the common wild duck. Did space allow, many other observations of equal interest might be quoted, but for these we must refer the reader to the work itself, which will form a welcome Christmas gift to all, whether young or old, interested in wild nature.

R. L.

DR. FRIEDRICH A. T. WINNECKE.

IT is always a painful duty to review the life work of those who have recently passed away, to estimate the position their names will occupy in the history of a science, and to survey the grounds on which their reputation will finally rest. But in the case of Dr. Winnecke, whose death was recorded last week, the task becomes both painful and difficult. Thirty years ago he occupied a prominent position among continental astronomers, and was intimately connected with the onward growth and development of the science in many important directions. His enterprise and ability were everywhere acknowledged, and a long career of work and usefulness seemed before him. But while he was still a comparatively young man, the state of his health prevented him from adding to the reputation he had established, and to-day his name is perhaps little more than a memory to many, who, interested in newer problems and more sensational inquiries, may possibly undervalue the work of an older school, which occupied itself mainly in the astronomy of position. But wherever a just and comprehensive view of astronomy as a whole is taken, Winnecke's work will be remembered with gratitude and admiration.

Dr. Winnecke enjoyed the advantage of admirable mathematical training under competent teachers. The school of Bessel was then in the ascendant, and the reputations of Encke and of Argelander were at their zenith; while in the district of Hanover, where Winnecke passed his early years, the memory of Herschel was still treasured, and helped to give direction to his astronomical tastes. He received his training in practical astronomy mainly at Bonn, under Argelander, where he became a proficient in the use of the heliometer, and with this instrument effected a complete triangulation of the stars in the Præsepe cluster, together with a thorough examination of the necessary constants of reduction. This latter part of the work he prepared himself for publication, but never printed, and it forms a painful commentary on his enfeebled energies to remember that this work never saw the light till many years after, when Dr. Schur proved himself an able and sympathetic coadjutor, and arranged the numerical portion of the research for general use. In 1858, Winnecke left Bonn for Pulkova, where he still interested himself in extra-meridional work. The fine series of observations of the great comet of 1861, which he followed until May 1862, long after it had ceased to be observed in other telescopes, and on which the final orbit rests, is a proof of both his energy and his observational skill. Cometary astronomy always had for him great attractions, and besides the periodic comet which bears his name, he found several others, receiving the prize of the Vienna Academy of Sciences for his cometary discoveries. At Pulkova, too, he took some part in the geodetic work arranged between Dr. Otto Struve, Argelander, and the late Astronomer Royal, for determining the differences of longitude between places on the great European arc of parallel, and, in conjunction with Colonel Forsch and Captain Zylinski, carried through that portion of the scheme which connects Haverford West with Nieuport and Bonn.

Winnecke also bestowed some attention on the problem of the sun's distance, which forty years ago was a burning question. Hansen and Le Verrier were contending for the rejection of Encke's value of the parallax as the outcome of mathematical investigations based on the lunar and planetary theories, and were supported by the result of Foucault's mechanical operations arranged to determine the velocity of light. Winnecke was among the first to perceive the importance of obtaining evidence from independent sources, and fully appreciated the value of utilising the observations of Mars as a new element in the discussion. The result of his investigation of the observations made at the 1862 opposition was to assign to the Solar Parallax a value of 8″·964, confirmed by Stone's result of 8″·932.

After leaving Pulkova, Winnecke settled for some years in Karlsruhe, where he was an industrious observer of comets and variable stars. On the conclusion of the Franco-German war, he was invited to take charge of the new observatory at Strassburg. The equipment of this observatory and the details of its arrangement are due to his superintendence, and it certainly ranks among the best arranged of continental observatories. While in the position of Director, Winnecke's health finally broke down, and for a great many years he has been unable to take any part in the management of the establishment he had so admirably fitted and equipped. W. E. P.

NOTES.

THE Physico-Chemical Institute of the University of Leipzig, of which Prof. W. Ostwald is director, will be formally opened by a ceremony to be held in the large lecture theatre of the Institute on January 3.

DR. HUGH GALT, acting Professor of Forensic Medicine and Public Health at Glasgow University, has for some time back been engaged in a research upon the starches, which is likely to prove of value to the Department of Public Health.

MR. JOHN MILNE writes that arrangements have been made for the establishment of horizontal pendulums, with photographic apparatus to record unfelt movements, at Toronto, Harvard, Philadelphia, Victoria, B.C., New Zealand (two), Batavia, Madras, Calcutta, Bombay, Mauritius, the Cape, Argentina, San Fernando, and Kew, whilst a number of other stations are under consideration. Seismograms have already been received from Toronto. At his station on the Isle of Wight, for purposes of comparison, Mr. Milne has also two horizontal pendulums writing on smoked paper, and very shortly a Darwin bifilar pendulum is to be established. To this will be added later a von Rebeur-Paschwitz apparatus, with which type of apparatus Mr. Milne worked for many years in Japan.

DR. CHARRIN has been appointed to succeed Prof. d'Arsonval in the chair of Medicine of the Collège de France.

A NEW branch of the Russian Geographical Society has just been opened at Tashkend, for Turkestan.

ON December 4 the friends and pupils of Dr. C. Cramer, the professor of botany at Zürich, celebrated the fortieth anniversary of his connection as teacher with the Polytechnic in that town.

PROF. DR. WILLI ULE has just taken over the editorship of the weekly scientific periodical *Die Natur*, which was founded by Dr. Otto Ule and Dr. Karl Müller, and is now in its forty-sixth year of publication.

WE regret to see the announcement of the death of Mr. Gardiner G. Hubbard, President of the National Geographic Society, Washington. The death is also announced of Dr. Campbell Morfit, formerly professor of applied chemistry in the University of Maryland, and one of the scientific advisers of the United States Government.

AT the close of a lecture delivered by Lieut. Peary in Edinburgh on Friday last, under the auspices of the Royal Scottish Geographical Society, Dr. J. N. Murray, on behalf of the Council of the Society, presented him with the medal of the Society in recognition of his work in the Arctic regions.

A BROOKLYN correspondent sends this item of news:—'Prof. Langley and Prof. Elfreth Watkins have constructed a flying machine designed to draw a railroad car. This has been tested for several days on the Medford branch of the Pennsylvania Railroad, near Mount Holly, N.J., and has drawn the car at the rate of six miles an hour. The machine is actuated by a gasoline engine, the power being applied to two propellers, about four feet long, which make 800 revolutions per minute. It is expected that machines can be constructed on this principle, which can draw cars at the usual railroad speed."

WE learn from *Science* that Dr. George H. Horn, the eminent entomologist, died at Philadelphia on November 25. He was one of the Secretaries of the Philosophical Society, and was formerly Corresponding Secretary of the Academy of Natural Sciences. He had been until recently professor in the University of Pennsylvania, though his connection with that institution was chiefly honorary. Dr. Horn was only fifty-eight years of age, and his death, following those of Cope and Allen, is a further severe loss to the city of Philadelphia and to science in America.

La Nature announces the death of Prof. A. Joly, director of the chemical laboratory of the École normale Supérieure, and professor in the Paris Faculty of Sciences. Born at Fontenay-sous-Bois in 1846, M. Joly entered the Normal School in 1866. When he left this school he became attached to Saint-Claire Deville's laboratory, and afterwards was professor of physics at the lycée Henri IV., which post he occupied until he was nominated sub-director of the laboratory of the Normal School. The titular director of the laboratory at that time was M. Debray. M. Joly next became instructor (maître de conférences) in chemistry at the Sorbonne, and then professor attached to the Faculty of Sciences of Paris. His works refer principally to the rare metals (niobium among others) and acids of phosphorus.

THE first ordinary meeting of the Röntgen Society was held on December 7, Dr. Gladstone, F.R.S., being in the chair. Mr. A. A. Campbell Swinton read a paper on "Adjustable X-ray Tubes," in which various methods were discussed for regulating the penetrative and other qualities of X-rays, and for compensating the unavoidable and troublesome variations in vacuum that are found to occur in practice. The paper was illustrated by numerous experiments, and several adjustable tubes of Mr. Swinton's design, embodying the improvements and principles enunciated, were shown in operation.

THE ninth Congress of Archæological Societies was held at Burlington House on December 1, the Right Hon. Viscount Dillon in the chair. The Hon. Secretary reported that the Committee had authorised the completion of Mr. Gomme's Index of Papers from 1682, with a view to immediate publication. It was reported that a wish had been expressed to have an index of the archæological articles in certain journals and publications, other than the *Transactions* of Societies. The Standing Committee had considered the subject, and recommended that if anything were done it should be by adding a supplement to the Index as now published. After discussion the question was referred to the Committee with power to act, if they found they could do so to advantage and at reasonable expense. It was resolved, on the motion of Sir John Evans, K.C.B.: "That a memorandum be sent to the various local Archæological Societies, suggesting the desirability of placing themselves in communication with the Ordnance Survey officers for their districts so as to promote the record on the surveys of the earthworks within their districts, and where possible to determine their age by excavations." Mr. C. Hercules Read, the Secretary of the Society of Antiquaries, made a statement as to the steps that had been taken by Government in response to the request of the Society of Antiquaries for information as to what is done in foreign countries for the protection of ancient and historical monuments. Full information had been obtained and would shortly be published in a Blue Book. It appears that in no country in Europe is so little protection given as in England. Mr. Hope read a draft report on the best mode of indexing the *Transactions* of Societies; this had been prepared by the Committee consisting of himself and Mr. J. H. Round and Mr. Gomme. As it appeared that several Societies were anxiously waiting for the recommendations, it was agreed that the report should be referred back to the Committee for final consideration, and that as soon as complete it should be issued to the Societies. The Hon. Secretary reported that a National Photographic Record Association had been formed under the presidency of Sir J. Benjamin Stone, M.P., who had been at the head of the original Warwickshire Survey. He was directed to communicate to the Association that "The Congress hears with great satisfaction of the formation of a National Photographic Record Society, and expresses its desire to assist the work in any way it can."

Mr. W. A. Knight, writing from Bruton, Somerset, informs us that on November 30, at 10.20 p.m., he was fortunate enough to observe there a splendid lunar rainbow. The moon was sufficiently near the horizon to give a large arc, and although it was scarcely quarter-full, the black clouds looming in the north-east made the bow appear quite bright. There appears to be no doubt that what Mr. Knight saw was a lunar rainbow and not a halo, for it was opposite the moon.

Prof. A. Riggenbach has sent us the results of seven years' rainfall observations at Basle, deduced from a self-recording gauge. Of course the period is very short, and in dealing with monthly and annual means the author combines the values with those of an ordinary gauge, giving altogether a series of thirty-three years. But the principal object of the paper is to bring out some interesting details, which cannot well be obtained from an ordinary gauge. Among these we may mention the frequency and duration of very heavy showers, the great majority of which last only about twenty minutes. Sixty per cent. of these occur between 1h. and 7h. p.m., and 87 per cent. occur between June and September. In the yearly range the rainfall probability reaches a maximum in the early summer and in the late autumn, while the minima fall in mid-summer and in the first months of the year. In the daily range the duration of rainfall reaches a maximum between 6h. and 8h. a.m., and falls to a shallow minimum at 7h. to 8h. p.m., after which it rises uniformly to the maximum again. The various phases are shown both in tabular and graphical form. Dr. Riggenbach is perhaps best known to English meteorologists by the success with which he has prosecuted cloud photography.

Herr Otto Baschin contributes to the *Verhandlungen der Gesellschaft für Erdkunde zu Berlin* an account of the fitting out and departure of Andrée's balloon expedition. The different possibilities as to the fate of the explorers are discussed, and the conclusion reached that there is as yet no reason to give up hope of their return. Under the most favourable circumstances the balloon might easily deposit its passengers on a part of Northern Siberia, from which it would take months to reach the nearest telegraph station.

The new number of the *Mittheilungen von Forschungsreisenden und Gelehrten aus den deutschen Schutzgebieten* contains some items of geographical interest. Dr. F. Stuhlmann contributes a paper on the German-Portuguese frontier in East Africa, with a new map of the mouth of the Ravuma. In the same region Lieut. Stadlbaur gives a short account of the Turu district and its people; whilst First Lieutenant Freiherr von Stein describes the Ossa or Lungasi lake, on a tributary of the Savaga in the Kameruns.

Different minds place different estimates on the intellectual accomplishments of the past half-century. In ordinary conversation the men of the mart will point to an Eiffel tower, a suspension bridge, a continental express train, a man-of-war, or an Atlantic cable. But in a discourse recently delivered in commemoration of the jubilee of the Sheffield Scientific School of Yale University, President Gilman remarked that perhaps the greatest triumphs of the intellect during the last half-century are these five contributions to human knowledge: the establishment of the principles of evolution; the establishment of the principle of the conservation of energy; the development of mathematical science and its application to physics, mechanics, electricity and astronomy; the development of spectrum analysis and the consequent discoveries respecting light and electricity; and the discovery of the nature and functions of bacteria, and of their influence, for weal or woe, upon living organisms.

As the result of an investigation of the red spectrum of argon, Dr. J. R. Rydberg comes to the conclusion (*Astrophysical Journal*, November) that it belongs to one single element. Moreover, there seems to him to be no reason to doubt that the blue spectrum belongs to the same element, but corresponds to a higher temperature. As to the supposed displacement of a great number of the lines of the white spectrum towards the red end of the spectrum, it is remarked, "nothing seems to indicate that we have to do with a *continuous* displacement, but rather with the appearance of new lines on the red side of those of the other spectra, with which they ought to be closely related. In such a case it seems most probable that the interesting observation of Eder and Valenta depends on a change in the relative intensity of two sets of connected lines."

In the *Philosophical Magazine* for December, Mr. J. D. Hamilton Dickson examines the relation between the electric resistance of a metallic wire and the temperature. Although it has been demonstrated that platinum is a suitable substance for determining temperatures over a very wide range, not much different probably from 2000° C., nevertheless, seeing that each platinum thermometer needs at least to have its constant specially and carefully determined, not by three, but by a series of observations, it cannot be too strongly urged that this work should in each case accompany the record of results when expressed in platinum temperatures; and no one will deny that to have these results expressed at once in terms of the normal air-thermometer will permanently enhance the value of the work in such a manner as to amply recompense the extra labour. With the view of helping towards this desirable end, Mr. Dickson proposes a formula of the form $(R+a)^2=p(t+b)$, where a, p, b are constants, and gives reasons for considering it as more representative of the connection between temperature and resistance than any formula hitherto proposed, and just as simple as any.

An interesting extension to space of n dimensions of Euler's and Meunier's theorems on the curvature of surfaces has been given by Signor Luigi Berzolari in the *Atti dei Lincei*, vi. 10. The author proves the following propositions:—Given in S_n a form of $n-1$ dimensions, the curvature (of Kronecker) at any point of any hyperplane section is equal to the curvature of the hyperplane section having the same trace on the tangent hyperplane at that point divided by the $n-2$th power of the cosine of the angle between the hyperplanes. The curvature of the normal hyperplane section at O is a maximum when the trace of the cutting hyperplane on the tangent hyperplane at O is one of the principal sections $S_n - 2$ of the indicatrix, and the sum of the curvatures of any $n-1$ hyperplane normal sections mutually at right angles is constant.

Determinations of the thermal conductivity of ice by different observers have hitherto exhibited a remarkable discrepancy of results, the values of this coefficient being, according to F. Neumann, 0·34; De la Rive, 0·14; Forbes, 0·134 and 0·128, according to direction; and, according to Mittchel, 0·30, the centimetre, gramme, minute and degree Centigrade being taken as units. In the *Atti dei Lincei*, vi. 9, Signor Paolo Straneo describes a simple method of determining this coefficient. From observations on two different kinds of ice, taking two different cubes of each, the values obtained are 0·307, 0·309 for one kind, 0·312 and 0·313 for the other. A further determination gives 0·304 for the first kind; hence, generally, k lies between 0·30 and 0·31. Noticing that certain kinds of ice are anistropic, the properties being different along the vertical and horizontal directions referred to the position when frozen, Signor Straneo, in a subsequent paper, investigates the question as to whether the thermal conductivity varies with the direction. In homogeneous amorphous ice the values for the vertical and horizontal directions were found to be practically equal (0·312 and 0·308), but homogeneous non-amorphous ice gave for the same directions 0·328 and 0·301 respectively in one experiment, and 0·325 and 0·308 in another, showing that only ice which is not perfectly amorphous presents small differences in the coefficient of conductivity in different directions.

THE physical aspect of the reversal of the photographic image is the subject of a suggestive paper by Captain Abney in the *Journal* of the Camera Club. To investigate the matter, a series of photo-micrographs of sections of films which had been given known exposures was taken. From these sections it is seen that the part of the films in which reversal has taken place are markedly different at the upper and lower surfaces. Near the upper surface the section shows comparatively fine grains of silver, whilst at the bottom surface it shows coarser grains. At the top part of the film, where the light has acted strongly, the reversal has taken place. At the bottom the light has not acted much more than usual, owing to the shielding action of the top part. When given areas of the film are examined, the numbers of separate silver particles are found to be very much the same in both cases, showing that there is a sort of normal number per volume which is subject to reduction, and that the main difference is in the *size* of the reduced particles. In the course of a discussion upon the subject of the paper, Dr. Armstrong, referring to the sections of the unreversed image, considered that Captain Abney had shown that to be the case which must be the case, and that so long as there was no reversal the particles must be practically as large as the bromide particles, and all of the same dimensions. By showing that the particles in the reversed image were so very much smaller, Captain Abney had contributed in an important degree to the solution of the character of the change that took place; it appeared to him that it had been shown that there was in some way a reconversion of the surface of the particle into soluble matter—that evidence had been adduced to prove that there must be a re-transference of the bromine back into the silver at the surface, leaving untouched the silver lower down in the particle, and consequently that when the fixing solution was applied, the particle became reduced in size.

AN article of perhaps no little interest to many persons in this country, and of some substantial importance to Spanish industries, is the so-called gut from silkworms. This is useful for fishing purposes, partly on account of its great tenacity and partly owing to its transparent quality, the line attaching the hook when in the water not being visible. The manner of obtaining this threadlike gut is described in the *Journal* of the Society of Arts as follows:—After the grub has eaten enough mulberry leaves and before it begins to spin, which is during the months of May and June, it is thrown into vinegar for several hours. The insect is killed, and the substance which the grub, if alive, would have spun into a cocoon, is forcibly drawn out from the dead body into a much thicker and shorter silken thread. Two thick threads (from each grub) are placed for about four hours in clear cold water, after which they are dipped for ten or fifteen minutes in a solution of some caustic, for which purpose soft soap dissolved in water is used. This serves to loosen a fine outer skin, which is next removed by the hands while the workman holds the thread between his teeth. The silk is then hung up to dry, care being taken to choose a shady place, as the sun has the effect of making them too brittle afterwards. In some parts of the country these silk guts are bleached with sulphur vapour, which makes them look beautifully glossy and snow-white, like spun glass, while those naturally dried retain always a yellowish tint.

THE current number of the *Annali d'Igiene Sperimentale* contains a note by Dr. Casagrandi on a yeast producing a red pigment which, in many respects, resembles the one described by Demme some years ago, and isolated by him from a cheese. Demme stated that his variety was not endowed with any fermentative properties; that isolated by Casagrandi, on the contrary, ferments glucose very readily. This fermentative power is not, however, a trustworthy one for establishing differences between very similar varieties of bacteria, for, as in other cases so in this, Casagrandi has found that Demme's yeast can be induced to ferment glucose if particular precautions are adopted. Both Demme's and Casagrandi's specimens are pathogenic to guinea-pigs, rabbits and rats, when subcutaneously introduced into these animals; whilst of much interest is the fact that when grown in milk they are both capable of so modifying the character of this liquid that dogs and rabbits fed with such milk develop diarrhœa, and the same symptoms have been observed in babies which had partaken of milk in which this red yeast had been growing. This yeast appears to be present in our surroundings, and may, therefore, at any time make its presence felt by obtaining access to milk if the latter is left unduly exposed. We already have one well-recognised red yeast, the so-called *Rosa hefe*, but Casagrandi does not claim that his variety is anything more than an offshoot from the second red yeast, known to us as the *Saccharomyces ruber* discovered by Demme some seven years ago.

NO. 11, vol. iii., of *Spelunca* contains, among much other cavern-lore, an illustrated account of M. Martel's explorations in the British Isles in 1895.

IN the November number of the *Irish Naturalist*, Mr. G. H. Kinahan urges the importance of a careful study of quartz-rocks, when not metamorphosed, with a view to the recognition of structures that may prove some of them to be of organic origin, like the modern sinter produced by the algæ of hot springs.

MR. W. JEROME HARRISON has reprinted, from the *Glacialists' Magazine*, "A Bibliography of Norfolk Glaciology," on the lines of his similar work on the Midlands. Over four hundred papers are catalogued, in approximate order of publication, and short abstracts of the most important are given. There is also a list of the Geological Survey maps, and an author-index. A reproduction of a photograph of one of the great chalk-masses in the drift of Runton forms a frontispiece to this useful reprint.

To commemorate the incorporation of the University College of Sheffield, a number of scientific papers by members of the College have been brought together and printed in a volume for private distribution. The subjects of physical papers included in the volume are:—The influence of carbon on iron, by Prof. J. O. Arnold; the preparation of pure iron by electrolysis, by Prof. W. M. Hicks, F.R.S., and Mr. L. T. O'Shea; vortex aggregates with gyrostatic quality, by Prof. Hicks; functions connected with tesseral harmonics, by Prof. A. H. Leahy; superheated steam-engine trials, by Prof. W. Ripper; the amount of carbonic anhydride in the atmosphere, by Prof. W. Carleton Williams; and contributions to the knowledge of the Triazole series, by Dr. George Young. In biological science there are papers on the comparative intellectual value of the anterior and posterior cerebral lobes, by Dr. C. Clapham; the development of the ovipositor in *Periplaneta orientalis*, by Prof. A. Denny;

the preparation of marine animals and plants as transparent lantern slides, by Prof. H. C. Sorby, F.R.S.; and the shape and position of the pancreas and the adjoining viscera, by Prof. C. Addison. The editing committee state that the volume "is presented as an earnest that the new College may in the future be distinguished, not only for the number of students it has trained, but also as a place for the advancement of knowledge." We accept the token, and from its character we are sure that the University College of Sheffield will not be behind in valuable contributions to science.

THE number of cuprous salts at present known is very small in comparison with the large number of stable cupric salts that can exist. The isolation of cuprous sulphate, in particular, has not yet been effected. In the current number of the *Comptes rendus* of the Paris Academy of Sciences there is an interesting account, by M. A. Joannis, of some attempts to isolate this salt, which, although unsuccessful, tend to prove that cuprous sulphate can be formed under certain conditions. Finely divided metallic copper digested with a solution of cupric sulphate, as is well known, undergoes no change. If, however, carbon monoxide is led in, a slow absorption takes place, the copper dissolving, and the solution becoming decolorised. These facts can be accounted for by assuming that cuprous sulphate is formed which combines with the carbon monoxide to form a compound analogous to that obtained from cuprous chloride. The decomposition of this solution when the gas is removed by the mercury pump is somewhat remarkable, for as soon as the pressure is reduced to about 2 mm. a pellicle of metallic copper forms on the surface, and the solution becomes blue, the reaction between cupric sulphate, copper, and carbonic oxide being in fact a reversible one and a function of the pressure of the gas.

FROM the December *Journal* of the Chemical Society, we derive the following particulars of a paper on the production of sugars in beetroot, by Friedrich Strohmer:—The opinion expressed thirty years ago by H. Schacht, that the quality of beetroots depends on the number of developed leaves and the length of life of the plant, is now shown to be free from objections. Sugar is produced in the leaves, either directly as reducing sugar, or from starch or other carbohydrate, and migrates through the leaf stems to the root. The production of sugar depends on the amount of light, and the form and position of the leaves are of importance. When the sunlight passed through white or yellow glass, leaf production was vigorous, but with blue or red glass feeble; and the weight of roots under the influence of yellow light was nearly twice as great as when blue and red light were employed. The percentage of sugar under the different conditions was 7·4–8·1 with yellow, 6·4–7·4 with red, and 8·0–8·4 with blue light. For producing total organic substance in beetroot, rays of medium wave-length are the most favourable, but for converting the products of assimilation into sugar, the so-called chemical rays seem to have a prominent *rôle*. The results of field experiments showed that sugar production begins at an early stage in the leaves, but is greatest from the beginning of August to the middle of September. Under favourable conditions, there may be a not inconsiderable accumulation of sugar even later. From the beginning of July, the sum of the percentages of water and sugar in the roots is constant. This, and the fact that the percentage of sugar in the roots increases until the leaves die, indicates that the sugar, once stored in the roots, remains there. It is only when the roots are taken out of the soil and the leaves cut off, that the sugar begins to be used up in maintaining the life of the plant and in preparation for second year's growth.

THE additions to the Zoological Society's Gardens during the past week include an Ocelot (*Felis pardalis*) from Para, presented by Mr. William Wethered; an Arctic Fox (*Canis lagopus*) from the Arctic Regions, presented by Mr. H. E. Wood; a Dominican's Cat (*Felis dominicanorum*), two White-legged Falconets (*Microhierax melanoleucus*), a White-browed Laughing Thrush (*Dryonastes sannoi*), a Collared Jay Thrush (*Garrulax picticollis*) from the province of Foochoo, China, presented by Messrs. C. B. Rickett and J. De la Touche; four Burrowing Owls (*Speotyto cunicularia*) from Argentina, presented by Miss Sandys Lumsdaine; a Common Chameleon (*Chamaeleon vulgaris*) from North Africa, presented by Miss M. L. Peake; a Golden Eagle (*Aquila chrysaetus*) from Newfoundland, two Black-necked Swans (*Cygnus nigricollis*, ♂ ♀) from Antarctic America, purchased; a Crested Porcupine (*Hystrix cristata*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OPPOSITIONS OF TWO MINOR PLANETS.—The minor planet Ceres will be in opposition to the sun on the 25th of this month. (For elements and coordinates see pages 2 and 3 of Appendix to Nautical Almanac 1897.) Although Ceres is the largest of the asteroids, it is interesting as having to give precedence to Vesta for brightness; the stellar magnitude at this opposition will be 7·1. Ceres is now describing a retrograde path on the borders of Auriga and Gemini, near ε Geminorum, and has therefore a considerable altitude.

There is also an opposition, on the 26th inst., of one of the fainter and less well-known minor planets, viz. Gerda, the elements and coordinates for which, as given by M. A. Iwanow, of Pulkova, will be found in *Astr. Nach.*, 3458. At the time of opposition the asteroid will be near to ν Geminorum.

THE TOTAL SOLAR ECLIPSE OF 1900.—Prevision is always a desirable attribute, and to an astronomer it is essential. We are reminded of this by an account given by Prof. Frank H. Bigelow, in the *Monthly Weather Review*, of the probable meteorological conditions along the path of the total eclipse of the sun, in the United States, on May 28, 1900. Beginning with May 15, of this year, and continuing until June 15, so as to include May 28 centrally, meteorological observations were made at sixty-six stations distributed uniformly over the portions of the States of Virginia, North Carolina, South Carolina, Georgia, Alabama, Mississippi, and Louisiana, crossed by the eclipse track. Observations were made of the general state of the sky at 8 a.m., 8.30 a.m. and 9 a.m., and also of the state of the sky near the sun. The results show that the conditions in the interior of Georgia and Alabama were better than in North Carolina, South Carolina, or Louisiana. Apparently it would be safer to establish eclipse stations in central Georgia or Alabama, upon the southern end of the Appalachian mountains, where the track crosses the elevated areas, than nearer the coast-line in either direction, north-eastward towards the Atlantic coast or south-westward towards the Gulf coast.

It is intended to repeat the observations during the years 1898 and 1899, so as to obtain as good information as possible with regard to suitable eclipse stations for the year 1900.

CORRECTED POSITION OF THE MOON.—It will be remembered that the Pleiades have been quite recently occulted twice by the moon, once in July and again in October. These occultations were specially observed at Lyons, and in No. 22 *Comptes rendus*, vol. cxxv., M. Lagrula shows that in a series of occultations of stars by the moon, observed at epochs sufficiently near together, it can be supposed that the corrections to apply to the tables of our satellite vary proportionally with the times. It is then possible from these to combine the equations of condition supplied by the different phenomena observed. Thus we can obtain with great precision the semi-diameter and the coordinates of the moon at the mean epoch, and even in certain cases her parallax. The two important occultations discussed are those which took place on July 23 and October 13, 1897. The results are given in the following table, where D and π represents the semi-diameter and the parallax of the moon at her mean distance; $\Delta\alpha$ and $\Delta\delta$ the corrections in R.A. and declination, which ought to be applied to the coordinates in Hansen's tables, corrected from Newcomb's numbers.

Paris Mean Time 1897 d. h. m.	D	ϖ	Δα	Δδ	No. of Obs.
July 23 13 9	15′ 32″·87 ± 0″·14	indeterminate	+ 0s·30 ± 0s·01	− 0″·1 ± 0″·2	36
Oct. 13 14 5	15′ 32″·86 ± 0″·24	57′ 3″·2 ± 1″·0	+ 0s·31 ± 0s·02	+ 0″·5 ± 0″·4	29

A NEW FORM OF MIRROR FOR A REFLECTING TELESCOPE.—During the dedication exercises held in connection with the Yerkes Observatory, Dr. C. L. Poor advocated and exhibited a reflecting telescope in which the mirror is a portion of a paraboloid of revolution cut from the surface near the extremity of the latus rectum. The reflected rays then being at right angles to the incident rays, no dome would be required for such a telescope, and there would be no secondary mirror. This form of telescope was, however, recommended by Prof. Pickering more than sixteen years ago (NATURE, 1881, August 25); moreover, Prof. Schaeberle shows in the *Astronomical Journal*, No. 419, the inefficiency of such an instrument, from the following considerations. Let L denote the distance from the focus to the centre of the mirror, which is evidently inclined about 45° to the line of sight. If D denotes the minimum diameter of this elliptical mirror, the maximum diameter must be D sec. 45° if a circular cone of rays is to be used. The linear distance from the focus to the nearest and most distant points of the mirror will then be approximately—

$$\text{Least distance} = L - \tfrac{1}{2} D \sec 45^\circ.$$
$$\text{Greatest distance} = L + \tfrac{1}{2} D \sec 45^\circ.$$

If we assume $\frac{L}{D} = \frac{7}{2}$, the greatest distance divided by the least distance becomes 1·22.

This quantity is approximately the *blurring factor* for the given ratio of focal length to aperture for this form of instrument. For a star which is only 5′ from the optical axis of the telescope, and in a place containing the longer axis of the mirror, the image will, therefore, be a line no less than 66″, or more than a minute of arc.

Exactly at the focal point this star image will be a point, but for all other positions of the image the definition will be unworkable.

RECENT RESEARCHES ON TERRESTRIAL MAGNETISM.[1]

THE science of terrestrial magnetism has on one previous occasion formed the topic of a Rede Lecture. Twenty-five years ago Sir E. Sabine delivered a discourse on this subject, with which his name will always be honourably connected. The length of time which has elapsed may perhaps justify a return to the same theme, though it must be admitted that now, as then, the study of the magnetic properties of the earth is in an early stage of development. It is true that considerable advances have been made in the theory of the nature of magnetism itself, and of its connection with electricity; but when we attempt to apply theory to explain the actual condition of the earth progress is at once checked by difficulties, many of which have hitherto proved insuperable. We have no real knowledge of why the earth is a magnet, no real knowledge as to why its magnetic state is continually changing, and thus we are compelled to spend long periods of time in collecting facts, which, though their number and complication oppress us, are still insufficient to answer some of the simplest questions that an inquirer, approaching the subject for the first time, would be sure to ask. Terrestrial magnetism is in this respect in the same stage as that occupied by astronomy during the centuries in which the data were accumulated on which Kepler and Newton worked. We have a certain grasp of the facts, but have not yet found the thread of theory which binds them together.

And in one respect the magnetician is less favourably situated than was the astronomer. The rapid repetition of the principal astronomical events made it comparatively easy to discover the laws which those events obey; but, though some magnetic phenomena run through their courses in a day, a year, or a short period of years, the greatest change of all, that which causes the magnet to point now to the east and now to the west of the geographical north, has been studied for three hundred years and is still unfinished. It is a secular variation, of which the period, if definite period there be, must be measured by ages, and centuries may yet elapse before the first cycle which man has watched will be complete.

In spite of these difficulties attempts are continually being made to draw from the facts at our disposal some more definite information as to the causes of terrestrial magnetism; to foretell the future from the present; to trace the connection between the magnetic state of the earth and the constitution of the sun or of the earth itself; and I propose, therefore, to bring before you some of the theories and speculations which are now attracting the attention of those who take special interest in this science.

The fundamental fact, or rather series of facts, from which we have to begin our investigation is a knowledge of the magnetic state of the surface of the earth. To determine this, observations have for many years past been made at many different places, at sea and on land. The general result is a matter of common knowledge. The compass needle points approximately north and south, and dips from the horizontal towards the magnetic poles of the earth.

The first and simplest hypothesis that will serve as a rough approximate explanation of these facts, is that the earth itself is uniformly magnetised, or that there is at the centre of the earth a small but very powerful magnet by which the compass and the dipping needle are controlled.

If this suggestion were adequate, we should be compelled to assume that the axis of the magnet was inclined to the axis of the earth, for the magnetic and geographical poles do not coincide. It would further follow that at the magnetic poles, where the dipping needle is vertical, the magnetic force, which determines the position of the needle, would be of maximum intensity.

But here the simple hypothesis breaks down. The distribution of terrestrial magnetism is more complex than that which can be thus explained. It is true that there are two magnetic poles, but the directive force is not greatest where the needle is vertical. On the contrary there are in each hemisphere two other points, generally called magnetic foci, at which the force is a maximum.

It is thus evident that the magnetic system of the earth might be better represented by supposing that there are within it two magnets inclined both to each other and to the geographical axis, that the foci indicate the directions of these axes, and that the magnetic pole or point where the needle stands vertical is determined by their joint action. Mr. H. Wilde attempted to imitate the magnetic state of the earth by the aid of a duplex arrangement of this kind, but even this was insufficient. He was compelled to supplement it by covering with thin sheets of iron those portions of the globe which correspond to the oceans, and with this modification he succeeded in making a capital magnetic model of the earth.

For the moment, however, I will not follow up the line of inquiry thus suggested, but will only draw attention to the fact that, in spite of all these complications, mathematical analysis supplies us with the means of answering certain questions as to the magnetic constitution of the earth, without the aid of a clear mental picture of the causes to which that magnetic state is due. Whether there be one or more independent magnetic systems within the globe, whether some portions are more magnetic than others, are points upon which at present we have but little information, but there are a few facts from which we can argue with the knowledge that the foundations of our investigation are secure.

Magnetic forces can be produced only by magnetised matter, or by electric currents, and these may either exist within the globe or be external to its surface. Some of the currents, however, may be both internal and external in the sense that their circuits pass partly through the rocks and partly through the air, and that at certain points they traverse the surface from earth to air or from air to earth. Thus the first important question with which the investigator is confronted is: Are the forces which act upon the compass produced within or without the globe? and, if the magnetic forces are in part due to electric currents, are all these currents wholly internal or wholly external, or do some of them flow in part within and in part without the earth?

With regard to the first inquiry, the great mathematician Gauss furnished us with a method by which, if our knowledge of the magnetic state of the surface of the earth is sufficiently accurate and extensive, we can determine the relative proportions of those parts of the force which are due to causes wholly external or internal respectively. It is only lately that a further attempt has been made to discover whether, in addition to these, currents from earth to air and from air to earth also exist. The credit of this attempt is due to Dr. A. Schmidt, who, taking the most recent and the most accurate facts at his disposal, deduced from them the conclusion that about one-fortieth part of the magnetic force is due to causes wholly external to the earth, and that a slightly larger fraction is produced by vertical currents; the origin of the remaining thirty-eight fortieths being traced to internal causes only.

---

[1] The "Rede Lecture" delivered in the Senate House, Cambridge, on June 9, by Prof. A. W. Rücker, F.R.S.

And now it becomes necessary to say a few words as to the method by which the vertical earth-air currents may be detected. If we could perform the impossible operation of severing the north pole of a magnet from the remainder without immediately producing poles of the opposite kind in the broken fragments, the isolated pole thus manufactured would be urged northwards by the magnetic forces which are in play near the surface of the earth. If therefore a traveller were to carry such a pole with him, he would be assisted when going northwards, retarded when returning to the south. If the tour ended at the starting-point, the advantage gained when moving in one direction would in general be exactly compensated by the disadvantage of being compelled to oppose the magnetic forces during the remainder of the journey.

To this rule there is one exception. If the migrations of the magnetic pole carried it round an electrical current, so that its course passed through the circuit in which the current flows, as a thread might pass through a ring, and if the route finally led back to the starting-point without again passing through the circuit of the current, the exact equilibrium of loss and gain would be destroyed, and when the journey was over the wandering pole would either have added to or drawn upon any store of energy which it might at first have possessed.

Whether the result would be a loss or a gain would depend upon the direction in which the journey was performed relatively to the direction of the current. On this point it is unnecessary to dwell. Suffice it to say that if the amount of the loss or gain experienced by a given pole is known, the magnitude and direction of the current, whose circuit had been traversed, can be calculated. The result would not be affected by whether the current flowed from all parts of the district which the path of the pole had encircled, or was confined to a few points only; the total flow would be registered without reference to how it was distributed. If some of the currents flowed in opposite directions the excess of one set over the other would be measured.

If now a current passes at a certain point from earth to air it must return from air to earth elsewhere, completing the circuit through the soil. The course of the unburied portion may be regarded as an aerial arch, and from what has been said it will be evident that if a magnetic pole were carried round a leg of this arch the circuit of the current would be pierced, and the total upward or downward flow would be determined. The experiment, as thus described, is impossible, but, by an appropriate method, we can determine the force which would be exerted at any point on the detached north pole of a magnet of given strength, and, if this be known for a sufficient number of points on the path, we can calculate what the result would be if the imaginary conditions of the journey could be realised.

The calculations of Dr. Schmidt as to the existence of earth-air currents were based upon this principle, and were applied to the earth as a whole. Their general accuracy has been confirmed by Dr. Bauer, who supposed the hypothetical isolated magnetic pole to be carried along lines of latitude right round the earth. If, for instance, the journey were made along latitude 51½°, beginning and ending at London, the resulting work would show the total amount of the currents which traverse the northern portions of the Northern Hemisphere between that latitude and the geographical pole. If the same operation were repeated, say on latitude 45°, a similar result would be obtained, and the difference between the two would give the average flow of the currents which traverse the surface of the earth between these two latitudes.

Of course, it must be remembered that by such a calculation we can only arrive at a mean result. If, for instance, we had proved that between these latitudes there was, on the whole, an upward current, it would by no means follow that at all points on the vast surface included between the selected boundaries the currents were flowing from below to above. The meaning of the result would be that, within the region considered, the upward were stronger than the downward currents, and that, if the excess were uniformly distributed over the whole of the surface to which the calculation applied, an average current of such and such a magnitude would be produced.

Turning from the method of detecting the vertical currents to the question as to whether they exist, there are, apart from the calculations of Schmidt and Bauer, some experimental and theoretical reasons which support an affirmative answer. We know that earth currents traverse the soil beneath us. The Aurora is evidence of electrical discharge in the atmosphere. It is conceivable that there are cross connections between these two systems. Again, if the immediate surroundings of the earth are electrically conducting, the mere rotation of the huge magnetic mass of the earth itself would cause the production of currents which at some points would flow out of, and at others would flow into the surface. The late Prof. Hertz calculated the forms of the paths of such currents for the case of a uniformly magnetised sphere rotating about its magnetic axis, and, though the fact that the magnetism of the earth is irregularly distributed forbids us to apply his calculation directly to the globe, yet the principle holds good, though the distribution of the currents would be more complex. Dr. Bauer has deduced from the calculations already referred to the average direction of flow between different latitudes.

The result is shown in Fig. 1. The directions and magnitudes of the supposed vertical currents are indicated by arrows, and points at which there are no such currents occur at lat. 43° N. and 40° S.

Up to this point, therefore, the argument seems all in favour of the actual existence of currents from earth to air, but the results of calculations such as these must be accepted with very great caution. Our knowledge of the magnetic state of the earth is very imperfect; we know but little of the oceans as compared with the land, and of the land but little of the less civilised regions. Whatever be the lines of latitude chosen they must pass over sea, or desert, or both; and if the assumptions made as to the magnetic conditions of these regions are incorrect, it may be that the results are due not to the physical existence of the currents, but to the inaccuracy of the data to which the formulæ were applied.

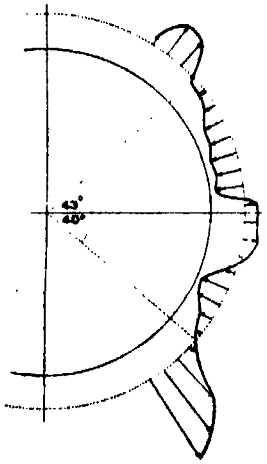

FIG. 1.

It therefore becomes important to check such large scale calculations by others which depend only on the comparatively small areas which have been minutely studied.

In 1895, Dr. Carlheim-Gyllensköld applied the test for the existence of vertical currents to Sweden, for which comparatively numerous observations could be utilised. The conclusion at which he arrived was that there was no evidence for the existence of the currents, except in those parts of the country where the data were so untrustworthy as to make any conclusion valueless.

In 1896 similar calculations were made for this country. Dr. Thorpe and I have recently completed a magnetic survey of the United Kingdom which is, I believe, the most complete of any which has hitherto been made of an equally large area. All our observations were made within a few years, and, therefore, the corrections for secular change were comparatively unimportant.

The survey was divided into two parts, in one of which we depicted the magnetic state of the kingdom in 1886; while the other part was devoted to a similar investigation for the epoch 1891. We were thus able to compare the results obtained at two periods, separated by a few years only, and by their concordance or disagreement to judge of the value of our conclusions. As these appear to be of some importance with regard to the question we are now discussing, I have recently repeated the calculations in a somewhat different way, and have determined the average value of the currents flowing through all the districts in the United Kingdom which are bounded by lines of latitude and longitude corresponding to whole degrees.

Thus, if starting on the meridian of Greenwich a traveller were to go due north from lat. 51° to 52°, that is from mid-Sussex to the north of Hertfordshire, then were to go due west until long. 1° W. was reached near Buckingham, thence due south along long. 1°, until when near Petersfield he turned homewards due east along lat. 51°, his route would include an area of, in round numbers, 2800 square miles, or of about 7000 square kilometres. In each such circuit the average current expressed in hundredths of an ampere per square kilometre has been determined, and the results are shown on maps both for 1886 and for 1891.

These maps are given in Fig. 2, A and B. The numbers indicate the average flow in hundredths of an ampere per square kilometre. The figures are underlined where the flow of the current is from above to below. In other cases the direction is upwards.

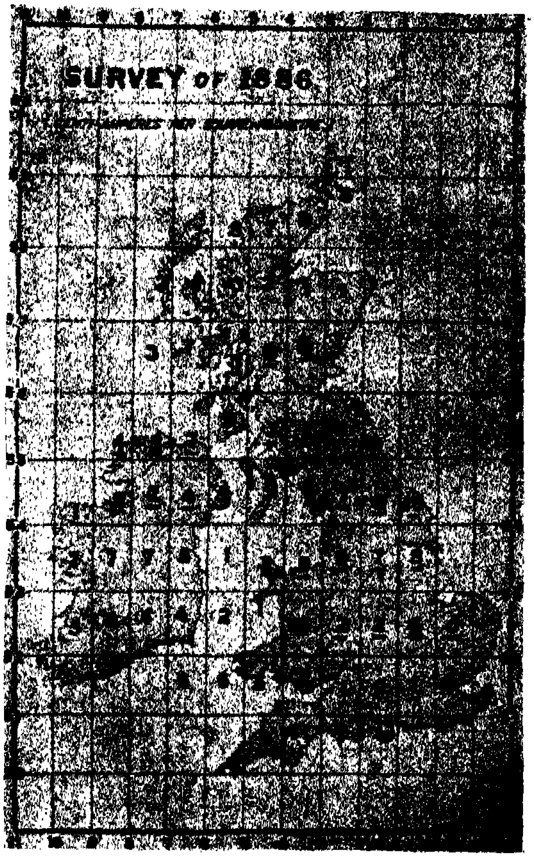

FIG. 2, A.

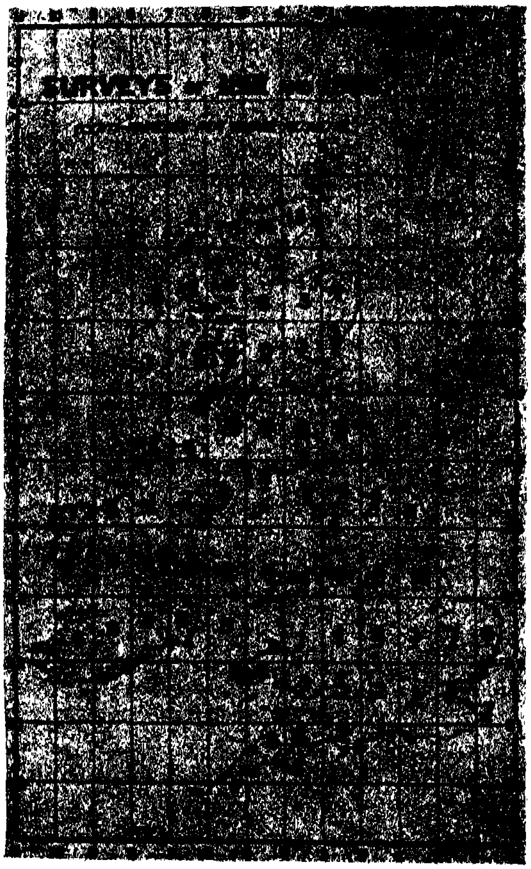

FIG. 2, B.

Fig. 2, A, shows the result for January 1, 1886, deduced from the 200 stations which were then available. In Fig. 2, B, all the facts obtained in the two surveys are worked up to a final result for the date January 1, 1891.

If we compare the two maps thus obtained from the two surveys, the conclusions arrived at are, in some respects, not very different. In both the larger currents occur near the boundaries of the land area to which the observations were necessarily confined. If the maps are to be trusted, the largest currents exist in the extreme north of Scotland, in the east of England, and in the far west of Ireland. It is also in favour of the trustworthiness of the results that in both cases the upward currents occur in the same parts of the kingdom. The figures indicate that the currents flow upwards in the far north, in the west and south, while in the midlands and the east the general tendency is from above to below.

But in spite of this apparent agreement, I am very doubtful whether these conclusions can be trusted. In the first place the currents are very minute. The whole flow of electricity passing through an area of 2800 square miles is less than that concentrated by Prof. Moissan in a few square inches within an electric furnace. The forces to be measured are so small that they must be seriously affected by the inevitable errors of observation and reduction.

Again, the observations which were made at nearly 900 places scattered all over the kingdom, are affected by local disturbances, due to quite other causes than those we are now discussing, and the magnetic state of the whole area, such as it would be if these disturbances were removed, can only be deduced by an elaborate system of averaging the results obtained at different places. This process of taking means is least accurate near the boundaries of the survey, and thus the larger currents which are indicated near the shores of our islands have probably no real physical existence, but are due only to the relative uncertainty of our knowledge of the magnetic state of the particular localities in which they appear to flow. From this point of view, therefore, it appears to be unsafe to trust to any particular figure, and that a better result will be obtained if we deal with larger areas and content ourselves with taking the mean of all the currents which appear to flow within them through the surface of the earth.

Adopting this plan, the general conclusions to be drawn from the two maps are very nearly identical. If for the moment we neglect the question as to whether the currents are flowing up or down, their average magnitude in any considerable area in the United Kingdom is about five-hundredths of an ampere per square kilometre. If, however, we take account, as we are bound to do, of the difference of direction, treating those which flow upwards as positive and those which flow down as negative, the result would show that the mean current in the United Kingdom is about five-thousandths of an ampere per square kilometre. Of course, if we deal with considerable but smaller areas, the precise value obtained depends upon the district chosen, but this does not affect the conclusion to any important extent. Thus, for the reason I have already given, it is probable that our knowledge of the magnetic state of the central districts is better than our information as to the borders, and if we confine ourselves to the centre of the kingdom, we find that the average current is downwards in both cases, and that in 1886 it was apparently a little larger, and in 1891 a little less than one-hundredth of an ampere per square kilometre.

Even these concordant conclusions are rendered more doubtful if the two completely independent sets of results obtained by means of the two surveys for 1886 to 1891, respectively, are reduced to the same date. It is true that the magnitudes of the calculated currents are larger than those shown in the map given above, but on the whole they are so opposed in direction that the comparison compels us to reject the hypothesis of their physical reality.

I therefore feel justified in asserting that no evidence that can be relied upon points to the existence of any flow of electric currents through the surface of the British Isles, whether from below to above or from above to below. The quantities are so minute that if they existed they could barely be measured, and the results are too discordant to command assent.

Since the survey of the United Kingdom was completed, my friend Dr. Van Rijckevorsel has made a minute magnetic survey of Holland. In the case of so small a district it is more difficult to eliminate the effects of local disturbances than when the area to be dealt with is larger, and thus I doubt whether conclusions as to the flow of electrical currents drawn from Holland alone could be regarded as trustworthy. Taking them, however, for what they are worth, they indicate an upward current of about one-tenth of an ampere per square kilometre for that country. All these quantities are less than the currents which Dr. Schmidt's calculations demand. In the neighbourhood of the United Kingdom the flow should, according to his calculations, be upwards and the magnitude about fifteen-hundredths of an ampere per square kilometre. This is approached by the flow in Holland, but is from ten to twenty times greater than the average obtained over large areas in the United Kingdom.

So far, then, the question as to whether such currents really exist appears to be doubtful. The calculations of Schmidt and Bauer lead to the conclusion that when the world as a whole is investigated the answer is affirmative, but all the more accurate investigations which have hitherto been made in small areas combine to prove either that the currents do not exist, or that they are less than Dr. Schmidt's theory demands. This fact, taken by itself, is not conclusive, as Sweden, the United Kingdom, and Holland are all in the west of Europe, and it might well be that this happened to be a district in which the currents were exceptionally small; but, on the other hand, the doubt thus raised is formidable. Dr. von Bezold has recently stated to the Berlin Academy that Dr. Schmidt himself must now be added to the list of doubters; and von Bezold confirms this caution by figures which lead him to the conclusion that in all probability the results obtained from calculations which embrace the whole globe are due rather to the want of accuracy of our knowledge than of the physical reality of currents from earth to air. I should myself be sorry to pronounce a final opinion, but I must confess that I seriously doubt whether the horizontal magnetic force has been determined with adequate accuracy at a sufficient number of places in the vast regions which are covered with the sea to enable us to draw any final conclusion from areas which include them, and I certainly consider that the balance of evidence is at present opposed to the physical reality of the currents. Before we can accept the opposite proposition some evidence must be produced based on surveys as complete as those of England and Holland. Before long we shall probably have full information as to France and Maryland, and it is possible that one or other of these may furnish positive evidence sufficient to outweigh the negative results which have hitherto been obtained.

(*To be continued.*)

A PROPOSED SWEDISH EXPEDITION TO THE ARCTIC REGIONS.

A YEAR since, Dr. A. G. Nathorst, of Stockholm, read a paper before the Swedish Society for Anthropology and Geology, entitled "Återblick på Polarforskningens närvarende Ställning samt Förslag till en Svensk Polarexpedition" (a review of the present position of Polar investigation, with a project for a Swedish Polar expedition), which has since been published in *Ymer* (Årgång 1896, Heft 4, pp. 267-286), the journal of the Society. At the time of reading the paper, there seemed but little probability of a near realisation of the projected scheme; but, during the present year, the King of Sweden and certain wealthy merchants of Stockholm and Gothenburg have generously come forward and provided the funds necessary for carrying it out, and Dr. Nathorst, who will act as the scientific leader of the expedition, is now engaged in preparations for a start next year (1898).

As the result of Nansen's voyage, Dr. Nathorst thinks that there is but little probability of the discovery of fresh land areas in the vicinity of the Pole, and that the aim of future expeditions to the Arctic regions should be a thorough scientific investigation of those lands, of which at present but little is known beyond the fact of their existence. Under this head may be mentioned the west coast of Ellesmere Land and Grinnell Land and the neighbouring islands; also the shores of Jones Sound, in Arctic America. Further, large tracts of the north-eastern and north-western coasts of Greenland remain to be examined, in spite of the admirable work of the Danish, Austrian, and other exploring expeditions. But it is with Spitsbergen and the region east of it that previous Polar explorations on the part of Sweden have been most closely connected; and though no fewer than twelve different Swedish expeditions, led by such men as Torell, Nordenskiöld, Nathorst, de Geer, and others, have visited this region since 1858, and that it has been the field of work for expeditions from other countries as well, the most recent being that under Sir Martin Conway in 1896, it yet offers, in Nathorst's opinion, a rich harvest for scientific investigation.

The west coast of Spitsbergen is now fairly well known, but owing to the ice coming from the east and blockading the eastern coasts of the island, nothing has as as yet been ascertained of their geological structure. The same obstacle has also prevented observations on Stans Foreland (Edge Island), Barentz Land, North East Land, Kung Karls Land, and Ny Island; but it is probable, that given favourable conditions of the ice, a steam vessel would be able to approach sufficiently near these islands to allow of their geology at least to be made out. The exploration of these lands between Spitsbergen and Franz Josef Land is the main object of the expedition; but should this be frustrated by the prevalence of the ice, the research work would be carried on in Spitsbergen itself, and more particularly a study would be made of the raised shell-banks and terraces, evidencing a comparatively recent elevation of the land, and of the remarkable quaternary deposits which show that the climate of the island, for a certain interval after the Ice age, was warmer than at the present time. Promising botanical results might be also expected from an examination of the valleys extending from the heads of the fiords, as, for example, those in Sassen Bay, Kol Bay, and Van Mijens Bay.

A stout vessel of from 350 to 400 tons, and a crew of thirteen men, would, in Nathorst's opinion, be most suitable for the undertaking; and the scientific staff would consist of a geologist, a botanist, two zoologists, one hydrographer and meteorologist, and one for cartography and photography. It is not intended to over-winter in the Arctic regions, but the vessel would be provisioned for a year, in case of accidents. The estimated cost of the expedition is about 4000*l.* It is proposed to reach Spitsbergen in the beginning of June, and work there until the middle of August, when it is hoped the ice will allow Kung Karls Land and the other islands near it to be examined.

THE USE OF KITES IN WEATHER PREDICTION.

THE systematic exploration of the upper air by means of kites is referred to by Prof. Cleveland Abbe in the *Monthly Weather Review*, at the end of a long article upon the experiments made previous to 1893. It is pointed out that at that time the Malay kite and the free balloon were merely looked upon as the means of occasionally obtaining isolated items of information from the upper regions; the world had not then awakened to the possibility of the work inaugurated by Prof. Moore in July 1895, which looks to the compilation of a daily map of simultaneous observations high above the earth's surface and over a large portion of the United States, for study in connection with the map of surface conditions. Observations of the air at a single station can have but little value compared with the international balloon work of Europe, or the extended national kite work of the U.S. Weather Bureau.

In an address at Toronto, before the British Association, Prof. Moore is reported by the *Review* to have said:

"For twenty-seven years the forecasters of the Weather Bureau have studied the inception, development, and progression of these different classes of atmospheric disturbances. From a knowledge personally gained by many years' service as an official forecaster, I do not hesitate to express the opinion that we have long since reached the highest degree of accuracy in the making of forecasts possible to be attained with surface readings. It is patent that we are extremely ignorant of the mechanics of the storm; of the operations of those vast yet subtle forces in free air which give inception to the disturbance, and which supply the energy necessary to continue the same. Long having realised this, I determined at once, on coming to the control of the United States Weather Bureau, to systematically attack the problem of upper-air exploration, with the hope ultimately of being able to construct a daily synoptic weather chart from simultaneous readings taken in free air at an altitude of not less than one mile above the earth. It appeared to me that all previous plans for investigating the upper air, by means of free and uncontrollable balloons, by observers in balloons, or by isolated kite stations or mountain observatories, were of little value in getting the information absolutely necessary to the improvement of our methods of forecasting. Simultaneous observations, at a uniform high level, from many co-operating kite stations, was the fundamental feature of the plan that I inaugurated for the prosecution of this important investigation.

"Prof. Marvin was assigned to the difficult task of devising appliances and making instruments, and I am pleased to say that we have improved on kite flying to such an extent that apparatus is now easily sent up to a height of one mile in only a moderate wind. We have made an automatic instrument that, while weighing less than two pounds, will record temperature, pressure, humidity, and wind velocity. By January next we expect to have not less than twenty stations placed between the Rocky Mountains and the Atlantic Ocean taking daily readings at an elevation of one mile or more.

"We shall then construct a chart from the high-level readings obtained at these twenty stations, and study the same in connection with the surface chart made at the same moment. As we shall thus be able to map out not only, as now, the horizontal gradients for the lower surface conditions, but in addition the simultaneous gradients for the upper level, and, what is of still more importance, shall be able to deduce from these, for any section of the atmosphere, the simultaneous vertical gradients of temperature, humidity, pressure, and wind velocity, we may confidently hope to better understand the development of storms and cold waves, and eventually improve the forecasts of their future course, extent, and rate of movement. It will be a fascinating study to note the progress of cold waves at the upper and lower levels, and to determine whether the changes in temperature do not first begin above. I am anxious to know the difference in temperature between the surface and the upper stratum in the four quadrants of the cyclone, and also of the anti-cyclone, especially when the storm or cold-wave conditions are intense. The vertical distribution of temperature in the several quadrants may give a clue to the future direction of movement of the disturbance."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

MISS EMILY PENROSE, principal of Bedford College, London, has been appointed principal of the Royal Holloway College, Egham.

MR. WM. H. SAGE and Dean Sage have presented to Cornell University the large residence of the late Mr. Henry W. Sage, at Ithaca, for a students' hospital, and will equip it and endow it with 100,000 dols. The residence is valued at 80,000 dols.

THE following resolution has been unanimously passed by the lecturers and teachers in the medical school of Guy's Hospital: "That the medical school of Guy's Hospital earnestly request Her Majesty's Government to reintroduce into Parliament the London University Commission Bill of 1897, and to pass it into law during the ensuing Session."

AMONG the institutions created during the last half-century for the promotion of scientific research and education, the Sheffield Scientific School of Yale College, New Haven, holds an honourable place. A review of the foundation of the School, and of the work of the distinguished investigators who have been connected with it, was given in a discourse delivered by President Gilman at the semi-centennial anniversary recently held. It was in 1847 that Profs. Silliman and Norton opened a laboratory on the College grounds for the purpose of practical instruction in the applications of science to the arts and agriculture. Thus was born the Sheffield Scientific School of Yale University. At first chemistry was alone; engineering soon found a place; mathematics, physics and astronomy joined the oligarchy; in due time, mineralogy, geology, physical geography, zoology, botany and physiology found a welcome; modern languages and literature, history and economics, became strong allies. While this evolution was going on, not a word was spoken in disparagement of classical culture, nor a word of religious controversy. From the beginning onwards the institution has been the department of a University which never suffered its love of letters to blind its eyes to the value of science. The School largely owes its success to its association with the fame, the fortune, and the followers of a great *alma mater*. Substantial advantages were bestowed by the mother upon her offspring; and the present high position which the School occupies shows that the child has deserved the encouragement it has received.

A MEETING was held at the University of London on Tuesday afternoon, the Chancellor (Lord Herschell) presiding, to discuss the proposed legislation on the University of London question. The *Times* reports that there were present, besides the Vice-Chancellor (Sir Henry Roscoe), representatives of the Corporation of the City, the Technical Education Board of the London County Council, the Royal Colleges of Physicians and Surgeons, the various medical schools, University College, King's College, Bedford College, the Royal College of Science, and the City and Guilds of London Institute. The Chancellor invited expression of opinion on the London University Commission Bill which the Government propose to reintroduce early in the Session. He said that the Bill embodied the compromise between the various parties hitherto in conflict, and that it was to receive the support of the Senate, as also of both parties in Convocation. The Chancellor further explained why no proposal for any new charter was within the range of practical politics, reconstitution at the hands of a statutory commission being the only remaining course. He therefore urged the acceptance of the compromise. Many of those present spoke in favour of the scheme, and urged that a deputation should wait upon the Vice-President of Council at an early date. The only objection came from one of the smaller medical schools, which declared its preference for the creation of a second University in London. The feeling of the conference was, however, entirely in favour of the reconstruction of the existing University. A deputation to the Government will be appointed as suggested to urge the passing of the Bill.

SCIENTIFIC SERIALS.

Bulletin of the American Mathematical Society, November 1897.—The number opens with an account, by Prof. Osgood, of the proceedings at the International Congress of Mathematicians held at Zürich in August last. The transactions of the Congress, which was attended by about two hundred mathematicians, together with the papers read, or presented, are to be published in full.—Prof. J. McMahon performs a like work for the Detroit meeting of the American Association for the Advancement of Science. An analysis of the twenty-one papers presented to the Section is given. One of these communications was an account of stereoscopic views of spherical catenaries and gyroscopic curves by Prof. Greenhill, who was present at the meeting, and to whom the Section "is also indebted for instructive remarks made in connection with many of the other papers." Then follow five papers read before the American Mathematical

Society, viz. before the Chicago Section (April 24, 1897): Quaternions as members of four-dimensional space, by Prof. A. S. Hathaway. Note on the invariants of n points, by Dr. E. O. Lovett, is another communication which was made at the same meeting.—Dr. Lovett contributes also a note on the fundamental theorems of Lie's theory of Continuous Groups (October 30). The object of the note is to call attention to a misapprehension, if not an error, in a paper, by J. E. Campbell, on a law of combination of operators bearing on the theory of continuous transformation groups, read at the March 11 meeting of the London Mathematical Society (*Proc.*, vol. xxviii. pp. 381–390). The fourth paper is one read at the Toronto meeting, August 16. It is an interesting short note by Prof. T. F Holgate, and is entitled, "A geometrical locus connected with a system of coaxial circles." The writer's object is to find the locus of points through which three lines can be drawn tangential to three circles of a coaxial system in pairs.—Condition that the line common to $n-1$ planes in an n space may pierce a given quadric surface in the same space, by Dr. V. Snyder, was read at the Detroit meeting mentioned above. The note is a generalisation of a proof recently given by the author (criteria for nodes in Dupin's cyclides) of the geometric significance of a certain determinant.—Dr. E. W. Brown gives a valuable analysis of Prof. H. Lamb's Hydrodynamics. Of this the reviewer writes: "The author is to be congratulated on the completion of a task which will earn him the gratitude of all those who are now, or may in the future be, interested in Hydrodynamics.—In the Notes are particulars of the British Association meeting at Toronto, in so far as it concerned mathematicians. —Other matters are a list of the mathematical courses for the winter semester (1897–98) in the Universities of Göttingen, Leipzig, Munich, Vienna and Strassburg.

IN the *Meteorologische Zeitschrift* for November, Dr. J. Hann gives the daily range of the meteorological elements at Cairo, deduced from the observations of the five years 1891–5, as published in the *Résumé Mensuel* of the observatory at Abbassieh. These values are of some interest, as Dr. Hann states that the monthly means contained in the tables give for the first time the true daily means for Cairo. The barometric range exhibits the small amplitudes for the latitude that have been noticed in other parts of the Mediterranean. The night minimum does not appear to fall below the daily mean throughout the year. The range of temperature shows no special peculiarities; it is greatest in June, and is greater in the dry spring than in the damp autumn. The daily range of wind force is noteworthy, especially during spring and autumn; during the year there is only a very slight variation at night-time, but in the afternoon there is a great increase in the force from winter to spring, and from summer to autumn. During the winter half-year the nights are clear, while cloud prevails at the middle part of the day; in the summer the morning hours are cloudiest, but from about noon the sky is almost cloudless. The influence of the overflow of the Nile in the autumn naturally affects the range of humidity.

IN the *Journal of Botany* for November and December, Mr. F. Townsend completes his monograph of the British forms of *Euphrasia*, of which he makes fourteen "species" founded on von Wettstein's monograph of the genus. It is accompanied by seven plates illustrating the habit of each "species," and details of the form of the flowers and leaves.—In a paper on "New and Critical Marine Algæ," Mr. E. A. L. Batters describes a number of species new to science, together with a new genus, of Florideæ, *Porphyrodiscus*, from Berwick, with the crustaceous habit of *Hildenbrandtia*.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 25.—"On certain Media for the Cultivation of the Bacillus of Tubercle."[1] By Dr. Arthur Ransome, F.R.S.

The following conclusions had been drawn from previous experiments:—

(1) That finely divided tuberculous matter, such as pure cultures of the bacillus, or tuberculous matter derived from sputum, in daylight and in free currents of air is rapidly deprived of virulence;

(2) That even in the dark, although the action is retarded, fresh air has still some disinfecting influence; and

(3) That in the absence of air, or in confined air, the bacillus retains its power for long periods of time.

These observations afforded an explanation of the immunity of certain places, and the danger of infection in others. They show that where tuberculous sputum is exposed to sufficient light and air, to deprive it of virulence before it can be dried up and powdered into dust, no danger of infection need be dreaded. It would appear further, from this research and others, that it is only when there is sufficient organic material in the air, derived from impure ground air, or from the reek of human bodies, that the tubercle bacillus can retain its existence and its virulent power.

But, in addition to the above-mentioned researches, it seemed desirable that an attempt should be made to ascertain what part was played respectively by the several forms of organic impurity that are present in insanitary dwellings. It was determined, therefore, to collect the aqueous vapours arising from the ground, or from human bodies, and to submit these products to the test of trying whether they would serve as cultivating media for the bacillus of tubercle.

By means of a simple freezing mixture of ice and salt it was easy to condense the aqueous vapour, both of the breath and that coming from ground air.

Some evidence was obtained with simple glycerine agar that the organic fluids facilitated cultivation to some extent. With the organic fluids there were only two failures, and growth was fairly rapid.

In the next series of trials, it was decided to use as the material bases some non-nitrogenous substance, and at length it was determined to use a particularly pure "filter-paper."

Some degree of success was attained in twelve out of fifteen specimens of the organic fluids.

The degree of growth was also much the same as in the previous series, though perhaps slightly less vigorous.

It was now determined to try to do without the help of the glycerine, which, as is well known, so greatly assists the ordinary cultivations of the bacillus. Accordingly, four tubes with simple filter-paper as the supporting medium, and condensed fluids, from the breath of a healthy person, and from that of a phthisical patient, as nutrient fluids, were inoculated, and no glycerine was added. In these tubes the same cultivation was used as in the previous experiments.

Shortly afterwards, two similar tubes with fluid from healthy breath alone, but with 5 per cent. of glycerine, were sown with the same cultivation, and were left at the ordinary temperature of the laboratory, about 21° C.

All of the former group took on active growth within four weeks, and one of the latter. In other words, it was proved that pure filter-paper, moistened with these condensed fluids, alone would suffice to nourish and promote the growth of the bacillus, and, further, that this growth would take place at ordinary temperatures. It may hence be concluded that when this organic fluid is present in ordinary dwellings, the bacillus may grow at the temperature of living rooms as well as at the temperature of 35° C.

Two sets of tubes were then prepared of condensed vapour from breath, and from ground air from a pure sandy soil. No glycerine was added; but for the solid medium, in some instances, the pure filter-paper was employed; in others, an ordinary lining paper, containing a little size, but carefully sterilised, was used.

Some of these were placed in the incubator at a temperature of 37° C., others were left in the dark at the ordinary temperature of the laboratory.

In many of the tubes a free growth was observed as early as the end of the first fortnight.

Out of the total number in this series of 37, in thirty six instances there was free growth on the medium employed, on both kinds of paper, and all kinds of condensed fluid. Eleven of them were grown at a temperature of about 20° C. In only one instance was there complete failure (vapour from healthy breath).

The bearing of these researches upon the subject of the prophylaxis against tuberculosis seems to be of some importance.

They prove that any one of the various organically charged vapours, whether coming from healthy or from diseased lungs, from the air of cellars, or from comparatively pure ground, forms an excellent cultivating medium for the bacillus of tubercle when kept away from the disinfecting influence of air and light.

---

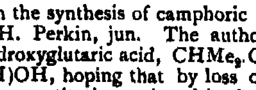
[1] By permission of the Royal College of Physicians, this research, which forms a portion of the Weber-Parkes prize essay, is communicated to the Royal Society before publication. The cost of the inquiry is defrayed by the Thruston prize, presented to the author this year by Gonville and Caius College, Cambridge.

This power of promoting its growth is particularly manifest when the supporting substance is common wall-paper, though it is quite apparent when very pure filter-paper is used.

It is further proved that, on these substances, the growth of the bacillus may take place at the ordinary temperatures of dwelling-rooms; and, hence, that there is no safety against the increase of the organism in ordinary living-rooms in which active tuberculous dust is present, and in which the natural disinfectants of the bacillus, fresh air and light, are not present in sufficient amount to destroy their virulence.

Physical Society, December 10.—Mr. Shelford Bidwell, President, in the chair.—Mr. Albert Campbell exhibited: (1) An experiment to illustrate alternate exchange of kinetic energy. Two brass spheres, each about one inch diameter, are suspended from the same point by equal wires. One of them is then thrown so as to describe a circular orbit. The second sphere, starting from rest, gradually takes up motion from the first sphere, and in turn describes a circular orbit. The first now comes to rest, and the reverse process takes place. This alternating action repeats itself until all the energy is lost in the wires. (2) An experiment to illustrate the low heat-conductivity of glass, and the expansion of glass by heat. A long tube is clamped at the lower end, in a vertical position. One side of it is then heated with the flame of a Bunsen burner, and the glass is observed to bend, moving over a fixed mark near the top of the tube. When the flame is withdrawn, the first position is quickly regained. Mr. Campbell then read a paper on "Temperature compensators for standard cells." Some account of the methods adopted by the author has already been published, he now describes the apparatus. The first compensating arrangement (3) can be used for keeping the potential-difference between two points of a conducting system constant at all room-temperatures. Or it can be adapted to modify the voltage of a standard cell to some convenient whole number. This arrangement (3) resembles a Wheatstone's bridge with the galvanometer-branch removed. One pair of opposite arms is of copper, the other pair is of manganin. The bridge-battery is a Leclanché cell; this supplies the auxiliary voltage, which is utilised at the two galvanometer-points of the bridge, and is there applied in series with the standard cell. In an alternative method, suggested by Mr. C. Crawley, only one of the four arms is made of copper. The second compensating arrangement (4) is intended to maintain constant potential between two points, at all room-temperatures. For this purpose, two wires, *a* and *b*, are connected in parallel. One of them, *a*, is all of manganin, the other, *b*, is partly copper and partly manganin. Constant *current* is applied at the ends of *a* and *b*. The various resistances are chosen so as to give constant difference of potential between the ends of the manganin portion of *b*. By this method the potential-difference can be maintained to within 1 in 2000. Mr. Swinburne said that twelve or thirteen years ago he had given a good deal of thought to compensation by wires of different temperature-coefficients. The first thing he tried was a Wheatstone's bridge. This was compensated by making the bridge-arms of wires whose temperature-coefficients differed—as, for instance, platinoid and copper. He then applied the same principle to the compensation of standard cells, using a potentiometer method that gave direct readings, and to the compensation of voltmeters and watt-meters. These results were published between 1885 and 1890, in the electrical journals. He believed that Mr. Evershed had also developed this idea, by putting "back" turns on voltmeters, and by other differential devices. The details of Mr. Campbell's apparatus had a few points of special interest. The way in which he connected up the bridge (3) seemed particularly worthy of notice. Prof. Ayrton asked whether thermo-electric effects produced difficulty in the compounded arrangement. Mr. Campbell said the system was symmetrical, and the thermal currents were consequently neutralised. Mr. Appleyard, referring to experiment (2), said it was identical with one that had been shown for the past eight years at lectures at Cooper's Hill College. It was specially of interest as illustrating the deflection that occurs with girders and bridges when exposed on one side to sunshine. —Mr. J. Rose-Innes read a mathematical paper on Lord Kelvin's absolute method of graduating a thermometer. Lord Kelvin has investigated the cooling effects exhibited by various gases in passing through a porous plug. He found that for any gas, kept at the same initial temperature, the cooling effects were proportional to the difference of pressure on the two sides of the plug. He also found that, for any one gas, the cooling effect per unit difference of pressure varies approximately as the inverse square of the absolute temperature. This rule holds very well in the case of air; it is not so satisfactory for carbonic acid; it fails for hydrogen. With hydrogen there is a *heating* effect that increases, if anything, when the temperature rises. Mr. Rose-Innes proposes an empirical formula, containing two disposable constants, α and β, characteristic of the gas in question. Denoting by T the absolute temperature, he finds that, very approximately, the cooling effect is given by the expression $(\alpha/T - \beta)$ This relation includes the three cases—air, hydrogen, carbonic acid—under one form, and thus enables them to be treated in one common investigation. Moreover, the differential equation concerned in the thermo-dynamic scale is thereby rendered more manageable; it leads to simpler algebraic results after integration. The paper discusses the thermo-dynamic correction for a constant-pressure gas-thermometer, and the correction for a constant-volume gas-thermometer; also an estimate of the absolute value of the freezing-point of water; the results obtained take, for the most part, a very simple shape, using the above expression for the cooling. Dr. S. P. Thompson said the empirical expression, $(\alpha/T - \beta)$, indicated that at some particular temperature the cooling effect vanished; that was a point suggestive of useful results if investigated by experiment. Mr. J. Walker read a communication from Mr. Baynes on the paper, and remarked upon the desirability of adopting two constants. He thought that further experiments should be made to discover how specific heat at constant temperature depends on temperature. The calculated values for hydrogen were too few to be taken as evidence of the validity of the rule. Mr. Rose-Innes, in reply, said that from what was known of hydrogen, it might be expected to behave at ordinary temperatures as air behaves at higher temperatures. His object was, if possible, to include in one formula the case of the three investigated gases. This was better than having a separate formula for each gas. Whether or not hydrogen was confirmatory with air and carbonic acid, might be considered as *sub judice*; it required further experimental data to test the formula in that case.—The President proposed a vote of thanks to the authors, and the meeting was adjourned until January 21, 1898.

Chemical Society, November 18.—Prof. Dewar, President, in the chair.—The following papers were read:—On the decomposition of camphoric acid by fusion with potash or soda, by A. W. Crossley and W. H. Perkin, jun. Camphoric acid, when fused with alkali, gives a mixture of a number of fatty acids with dihydrocamphoric acid, $C_{10}H_{18}O_4$, pseudocamphoric acid, $C_{10}H_{18}O_4$, and an acid of the composition $C_9H_{16}O_4$; the results are explained and constitutions assigned on the assumption that camphoric acid has the constitution,



$$\begin{matrix} CH_2.CH(COOH) \\ | \\ CMe_2.CMe(COOH) \end{matrix}\!\!>\!CH_2.$$

—Experiments on the synthesis of camphoric acid, by W. H. Bentley and W. H. Perkin, jun. The authors have prepared isobutylmethylhydroxyglutaric acid, $CHMe_2.CH_2.CH(COOH).CH_2.CMe(COOH)OH$, hoping that by loss of water it would give an acid of the constitution assigned in the previous paper to camphoric acid; by loss of water, however, a lactonic acid or its derivatives were usually obtained.—Synthesis of an isomeride of camphoronic acid, by S. B. Schryver.—The action of magnesium on cupric sulphate solution, by F. Clowes and R. M. Caven. When magnesium acts on copper sulphate solution, hydrogen, cuprous oxide, and copper are produced.—Properties and relationships of dihydroxytartaric acid, by H. J. H. Fenton. Dihydroxytartaric acid is readily prepared by oxidising dihydroxymaleic acid in aqueous solution; it gives a quantitative yield of tartronic acid on heating.—The molecular association of liquids and its influence on the osmotic pressure, by H. Crompton. The author shows that Planck and van Laar's demonstrations that association can have no effect on osmotic pressure are invalid owing to faulty reasoning.

Geological Society, December 1.—Dr. Henry Hicks, F.R.S., President, in the chair.—A revindication of the Llanberis unconformity, by the Rev. J. F. Blake. In a paper published in the *Quarterly Journal* of the Society for 1893, the author of the present paper maintained that certain conglomerates and associated rocks occurring for some distance north east and south-west of Llanberis, which had hitherto been considered to lie below the workable slates of the Cambrian rocks of that area, were in reality unconformable deposits of later date than those slates. In the year 1894 a paper appeared in the same journal, in which the authors maintained that in no case which had been examined could any valid evidence be found in favour of the alleged unconformity, and that in one (on the north-east side of Llyn Padarn) which they supposed to afford the most satisfactory proof of it, the facts were wholly opposed to the notion. The present paper was a reply to these authors, in which their objections, founded on general considerations, on field observations, and on microscopic examination of rock-specimens, were discussed, and the author gave the results of further observations on the rocks of the district.—The geology of Lambay Island, Co. Dublin, by Messrs. C. I. Gardiner and S. H. Reynolds. The authors, who have previously described the neighbouring district of Portraine (*Quart. Journ.* Geol. Soc., December 1897), undertook an examination of this island, with the intention of comparing the rocks with those of Portraine, and of investigating the nature of the rock familiar to geologists under the name of "Lambay porphyry." The sedimentary rocks are similar to some of those of Portraine, and are of Middle or Upper Bala age. Associated with them are pyroclastic rocks and andesitic lava-flows, some of the lavas having flowed beneath the sea. The sediments and volcanic rocks were exposed to denudation, and a conglomerate composed of their fragments was accumulated round the volcano. The "Lambay porphyry," which has been determined as a diabase-porphyry by Dr. von Lasaulx, is partly intrusive in the other rocks, but has in places come to the surface as a lava-flow. Petrographical descriptions of the various rocks were given by the authors.

Mathematical Society, December 9.—Prof. Elliott, F.R.S., President, in the chair.—Miss F. Hardcastle communicated a theorem concerning the special systems of point groups on a particular type of base curve.—Mr. Love, F.R.S., gave a sketch of a paper, by Prof. W. Burnside, F.R.S., on the straight line joining two given points.—Impromptu communications were made by Messrs. F. S. Macaulay, A. Berry, and E. T. Whittaker.

Entomological Society, December 1.—Mr. R. Trimen, F.R.S., President, in the chair.—Mr. Dudley Wright exhibited an aberration of *Argynnis euphrosyne*, in which the upperside was suffused with black, and the silver spots of the underside of the hindwings converted into streaks.—On behalf of Mr. W. H. Tuck, Mr. Tutt showed examples of *Metœcus paradoxus*, L., taken in nests of *Vespa vulgaris* near Bury St. Edmunds, together with some of the cells in which they were found. About a fifth of the nests examined were affected, some containing as many as twenty-four, twelve and eight examples of the beetle; the more usual number present was from two to four. The dates between which examples were taken in 1897 were from August 2 to October 1. According to Dr. Chapman the eggs were laid in the cracks of posts, &c., from which the wasps got the pulp to make their cells.—Combs were also exhibited from nests of *Vespa crabro* and *Vespa germanica*, in which Mr. Tuck had found larvæ of *Velleius dilatatus*, Fabr., which, however, he had been unable to rear.—The Rev. A. E. Eaton exhibited a specimen of the singular *Myodites subdipterus*, Fabr., taken by himself at Biskra, Algeria, and a near ally of *Metœcus*.—Mr. Blandford called attention to a new instance of the destructive propensities of *Dermestes vulpinus*, Fabr. He had received examples found at Hong-Kong among flags made of bunting, which were presumably injured, although no details had been forwarded. This form of injury was analogous with the damage to woodwork recorded by himself and others; it had nothing to do with the feeding-habits of the insect, but was committed by the larvæ in their search for shelter in which to pupate. Probably the flags had been stored at some period in the neighbourhood of infested leather goods, or dried provisions. The only other case of damage to textile fabrics by *Dermestes vulpinus* which he knew of occurred in connection with the case recorded by him (*Proc. Ent. Soc. Lond.*, 1890, p. xxxi); a blue handkerchief spotted with white, left in the infested building, was found next day to have all the white spots eaten out.—Mr. Champion communicated papers entitled "Notes on American and other Tingitidæ, with descriptions of two new genera and four species," and "A list of the Staphylinidæ collected by Mr. J. J. Walker, R.N., in the Straits of Gibraltar."

PARIS.

Academy of Sciences, December 6.—M. A. Chatin in the chair.—On the stability of the Eiffel tower, by M. Bassot. The paper is accompanied by four diagrams, showing the motion of the summit of the tower. The conclusion is drawn from these curves, that to verify by periodic observations any permanent displacement undergone by the summit, the measurements should be taken in the evening, two or three hours before sunset, as at that time the irregular movements are at a minimum.—On double integrals of the second species in the theory of algebraic surfaces, by M. Émile Picard.—The first modifications which occur in the fixed cells of the cornea, in the neighbourhood of wounds of that membrane, by M. L. Ranvier. A section is cut perpendicularly to the incisions made in the living animal, and gold staining applied until the fixed cells are nearly black. Those cells which have been cut by the knife at the end of twenty-four hours show budding prolongations by the edges of the wound. These phenomena exhibited by the cells of the cornea of the rabbit are of the same order as the extension by budding of the cylinder axes of cut nerve cells.—On the contamination of wells, by M. Duclaux. By an analytical study of the waters from the shallow wells of a village lately subject to a slight typhoid epidemic, it is shown that a comparatively simple chemical analysis suffices to distinguish between polluted and unpolluted wells, provided that the composition of the water of the district in a pure state is known. The bacteriological method of examination is looked upon as less trustworthy than the chemical method.—Actinometric observations made upon Mont Blanc, by MM. Crova and Hansky. The measurements were carried out in August and September, and were much interfered with by rain. At the summit the maximum value of the solar constant was 3·4, and it is suggested that under more favourable conditions this magnitude might be increased to 4·0.—Observations on the planet (DL) Charlois (1897, November 23) made at the Observatory of Toulouse (Brunner equatorial), by M. F. Rossard.—Application of the method of least squares to the detection of systematic errors, by M. Jean Mascart. A discussion of the conditions under which the application of the method of least squares becomes illusory.—On the approximation of functions of large numbers, by M. Maurice Hamy.—On associated pencils, by M. C. Guichard.—On the focal planes of a curve plane to one or several axes of symmetry, by M. P. H. Schoute.—On the existence of integrals in certain differential systems, by M. Riquier. Elliptical vibrations in fluids, by M. V. Crémieu.—The interference in air of two sound waves of different phases has been studied by observing the motion of a quartz fibre placed at the point of intersection of the waves.—On the dissociation and polymerisation of gases and vapours. Supposed dissociation of chlorine at high temperatures, by M. A. Leduc. The only evidence in favour of the dissociation of chlorine is one isolated observation of M. Crafts at 1400° C.—On the electric conductivity of discontinuous conducting substances, in relation to telegraphy without wires, by M. Édouard Branly.—On the transformation of the X-rays by metals, by M. G. Sagnac. If a bundle of X-rays is allowed to impinge upon a polished metallic surface, such as steel, or a mercury bath, there is no appreciable regular reflexion, but rays, termed by the author secondary rays, can be shown photographically or electrically to be diffused from the surfaces. These radiations show generally all the properties of the original X-rays, but the nature of the metal is not without influence, as the secondary rays from different metals can be distinguished by their unequal transmission by the same substance.—Some new facts observed in Crookes' tubes, by M. Virgilio Machado.—On the accidental causes of irreversibility in chemical reactions, by M. A. Colson. Two reactions are described in detail: the decomposition of normal phosphates by hydrochloric acid, and that of silver sulphate by hydrogen sulphide. In both cases secondary reactions intervene, which render the reversibility of the phenomena impossible.—On the existence of a cuprous sulphate, by M. A. Joannis (see p. 159).—On the elementary unity of the body called cerium, by MM. Wyrouboff and A. Verneuil. A criticism of the results of M. Boudouard, whose atomic weight determinations are stated to be affected both by impurities in his material, and inaccuracy in experimental work.—On aldehyde ammonia, by M. Marcel Delépine. Aldehyde ammonia, when left for three days in a vacuum over sulphuric acid, loses water, giving brilliant white crystals of a new base, ethylidene-imine, which analysis and cryoscopic estimations show to have the formula $(CH_3-CH=NH)_3$. A solution of aldehyde-ammonia in absolute alcohol gives a crystallised picrate of the same base.—On a reaction peculiar to orthophenols, and on the derivatives of antimonylpyrocatechol, by M. H. Causse.—On the nature of the combinations of antipyrine with aldehydes, by M. G. Patein.—Physiological and therapeutic effects of spermine, by M. Alexander Pœhl. The effects of the alkaloid are uniform, and consist in accelerating the phenomena of oxidation, thus favouring the elimination in the form of harmless products of several poisonous organic secretions.—Disappearance of lead poisoning by the partial substitution of metastannic acid in the putty used in glass polishing, by M. L. Guéroult. The original putty contained 62 per cent. of lead; by the addition of metastannic acid the lead was reduced to 20 per cent. During the six years in which this modified powder has been used, there have been no symptoms of lead poisoning in any form, although, with the original putty, saturnine paralysis was frequent.—On some new colloidal substances, analogous to albuminoids, derived from a nucleo-albumin, by M. J. W. Pickering.—On the development of *Trombidion holosericeum*, by M. S. Jourdain.—Observations on the *Rougets*, by M. P. Mégnin.—Researches on red granules, by MM. J. Kunstler and P. Busquet.—The formations included under the name of red granules appear to be due to a diffraction phenomenon, and have no morphological value.—On a ferment of cellulose, by M. V. Oméliansky.—On the decomposition of chloroform in the organism, by MM. A. Desgrez and M. Nicloux. Experiments are described tending to show that during anæsthesia by chloroform some carbon monoxide is produced by the action of the latter upon blood.—On some comparative results of ordinary clinical methods and fluoroscopic examination in pleuretic effusions, by MM. Bergonié and Carrière. The examination by means of the Röntgen rays is valuable in many ways as a supplement to the ordinary clinical methods.—Antagonism between the venom of the *Vespidæ* and that of the viper; the first vaccinates against the second, by M. C. Phisalix.—Permeability of the trunks of trees to atmospheric air, by M. Henri Devaux.—On the disease of chestnuts, by M. E. Roze.—Characteristics of a gas coal found in the northern coal field of New South Wales, by M. C. Eg. Bertrand.—On the fauna of the siderolithic Eocene beds of Lissieu (Rhône), by MM. Ernest Chantre and C. Gaillard.—Mechanical determination of the mean direction of the wind, by M. Louis Besson.

DIARY OF SOCIETIES.

THURSDAY, December 16.

Royal Society, at 4.30.—On a Method of Determining the Reactions at the Points of Support of Continuous Beams: G. Wilson.—The Comparative Chemistry of the Suprarenal Capsules: B. Moore and Swale Vincent.—Memoir on the Integration of Partial Differential Equations of the Second Order in Three Independent Variables: Prof. Forsyth, F.R.S.—On the Biology of *Stereum hirsutum*, Fr.: Prof. H. Marshall Ward, F.R.S.—An Examination into the Registered Speeds of American Trotting Horses, with Remarks on their Value as Hereditary Data: F. Galton, F.R.S.—On the Thermal Conductivities of Pure and Mixed Solids and Liquids, and their Variation with Temperature: Dr. C. H. Lees.—Cloudiness: Note on a Novel Case of Frequency: Prof. Pearson, F.R.S.—On the Occlusion of Hydrogen and Oxygen by Palladium: Dr. Mond, F.R.S., Prof. Ramsay, F.R.S., and Dr. J. Shields.—The Relations between Marine, Animal, and Vegetable Life: H. M. Vernon.

Linnean Society, at 8.—On the Affinities of the Madreporarian Genus Alveopora: H. M. Bernard.—On West Indian Characeæ collected by T. B. Blow: H. and J. Groves.

Chemical Society, at 8.—Stereo-Chemistry of Unsaturated Compounds. Part I. Esterification of Substituted Acrylic Acids: Dr. J. J. Sudborough and Lorenzo Lloyd.—Formation and Hydrolysis of Esters: Dr. J. J. Sudborough and M. E. Feilmann.—A New Method of Determining Freezing Points of very Dilute Solutions: Dr. M. Wilderman.

FRIDAY, December 17.

Institution of Electrical Engineers (Chemical Society's Rooms), at 8.—Accumulator Traction on Rails and Ordinary Roads: L. Epstein.

Institution of Civil Engineers, at 8.—The Elastic Properties of Steel Wire: Archer D. Keigwin.—The Elasticity of Portland Cement: W. L. Brown.

Epidemiological Society, at 8.30.—The Physical and Ethnological Conditions under which Leprosy occurs in China, the East Indian Archipelago, and Oceania: Dr. James Cantlie.

SUNDAY, December 19.

Sunday Lecture Society, at 4.—Some Animal Co-operative Societies: Dr. Andrew Wilson.

MONDAY, December 20.

Royal Geographical Society, at 8.30.

Imperial Institute, at 8.30.—Petroleum Sources of the British Empire: Boverton Redwood.

TUESDAY, December 21.

Institution of Civil Engineers, at 8.—A New Transmission Dynamometer: Prof. W. E. Dalby.

Royal Photographic Society, at 8.—Photomechanical Printing in Connection with the Survey of India: Colonel Waterhouse.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—Agriculture in some of its Relations to Chemistry: Prof. F. H. Storer, 3 Vols., 7th edition (Low).—A Run round the Empire: Dr. A. Hill (Sonnenschein).—Studies in the Psychology of Sex, H. Ellis. Vol. 1. Sexual Inversion (Watford, University Press).—La Pratique du Teinturier; J. Garçon, tome 3 (Paris, Gauthier-Villars).—Annuario publicado pelo Observatorio do Rio de Janeiro, 1897 (Rio de Janeiro).—Whittaker's Mechanical Engineer's Pocket-Book: P. R. Björling (Whittaker).—All about Animals (Newnes).—Rainfall Tables of the British Islands, 1866–1890 (Eyre).—Das Problem der Krystallisation: A. Turner (Leipzig, Thomas).—Die Kraft und Materie im Raume: A. Turner, Fünfte Verte Auflage (Leipzig, Thomas).—Arii e Italici: G. Serg (Torino, Fratelli Bocca).—*Meteorological Observations made at the Adelaide Observatory*, &c., during 1894 (Adelaide).—Annuaire 1898: par le Bureau des Longitudes (Paris, Gauthier-Villars).—Sir James Young Simpson and Chloroform (1811–1870): H. L. Gordon (Unwin).

Pamphlets.—Human Nature, its Principles and the Principles of Physiognomy: "Physicist." Part 1 (Churchill).—Of Atmospheres upon Planets and Satellites: Dr. G. J. Stoney (Williams).—On *Chlamydoselachus anguineus*, Garm., a Remarkable Shark found in Norway, 1896: R. Collett (Christiania).—Rainfall of the United States (Washington).

Serials.—Observatory, December, and Companion (Taylor).—Strand Magazine, December (Newnes).—American Naturalist, November (Philadelphia).—Mazama: a Record of Mountaineering in the Pacific Northwest, Vol. 1, No. 2 (Portland, Oregon).—American Journal of Science, December (New Haven).—Atlantic Monthly, December (Gay).—Bulletin de l'Académie Royale des Sciences, &c., de Belgique, 1897, Nos. 9 and 10 (Bruxelles).—Journal of the Anthropological Institute, November (Paul).—Journal of the Chemical Society, December (Gurney).—Engineering Magazine, December (222 Strand).—Astrophysical Journal, November (Chicago).—Monthly Weather Review, September (Washington).

THE GROWTH OF GEOLOGICAL IDEAS.

The Founders of Geology. By Sir Archibald Geikie. Pp. x + 297. (London: Macmillan and Co., Ltd., 1897.)

THE truths of science cannot be more impressively taught than by a sketch of the process by which the knowledge has been arrived at, and in no way can that history be more forcibly conveyed than in the biographies of those pioneers who first interpreted the phenomena for us. We may have wondered why the truth was not sooner grasped, but by this method of treating the subject we see what imperfection of evidence or prejudice stood in the way, and learn to appreciate the true spirit of original research which eventually rises above and overcomes all difficulties.

Sir Archibald Geikie has given a sketch of the founders of geology in his, now happily well-known, lucid style. It is necessarily only a selection, and accident or design has led him to make such a selection of points in the development of the subject as has enabled him to write what may be called an "appreciation" of the French school of geologists, and to dwell very fully on the work of some of them whose claims to recognition have hitherto been too much overlooked.

In the earlier stages of research all those who studied the composition of the earth's crust were called mineralogists, and any stony fragments which they dug out of the earth were their fossils. When men began to distinguish between bodies of organic and inorganic origin, they spoke of the pieces of rock and other mineral matter as *native* fossils, considering them as part of the original mass, while they called the remains of plants and animals *extraneous* fossils. It was only in comparatively recent times that the word fossil was applied exclusively to the remains of organisms. When the older writers speculated upon the manner in which the earth's crust had been brought into its present condition, they entitled their results "theories of the earth," which corresponded generally to our modern works on the principles of geology. Though they too often generalised on insufficient data, or wrested their judgment to support an early-formed opinion, they all pretended that their theories were founded on the study of nature; but we find many a good observation and sound inference buried under such a load of bad reasoning, and accompanied by such a cloud of foolish observations, that the writer's credit as a witness was destroyed, and even what was good in him lost sight of.

Our author passes with very brief notice over all the writers earlier than the eighteenth century, and devotes the greater part of his first lecture to a sketch of the work of Guettard: in a few clever touches he brings before us the personality of that remarkable man. Guettard first put into practice the proposal made by Lister in 1683, and constructed a map on which he showed the general surface distribution of the various kinds of rock as they occurred in broad belts in and around the Paris Basin, and even marked on it the places where he had found fossils. Later on, when a good topographical map of France had been produced, he indicated on it the characters of the rock over a very large area, completing the mineralogical survey of no fewer than sixteen sheets of the map. This was a work of great labour, and one involving very close observation, especially as he does not seem to have had any clear idea of the sequence of formations or of geological structure to guide him. Guettard was the first to recognise the ancient volcanoes of Auvergne, and deserves great credit for his able memoir on the meaning of the occurrence of the remains of shells and other organisms in the rocks. But the battle had long been raging between those who maintained that the fossils were mere *lusus naturæ*, and those who held that they represented plants and animals which once lived under conditions analogous to those of recent times, and were buried, as are dead organisms, in the mud and sand of to-day. In this long controversy many Italian and English geologists did good service, notably Agostino Scilla and Dr. John Woodward, who combated especially the erroneous views of Dr. Elie Camerarius; and although their work was hampered by the attempt to accommodate all their explanations to the received interpretation of the Scriptural account of the deluge, still the search for facts to support their theories helped on the work by calling attention to phenomena which might otherwise have long passed unobserved.

In his second lecture our author gives a sketch of the life and work of Desmarest. He tells us of the difficulties and struggles of his early life; of his official work in connection with the efforts made by the French Government in the middle of the last century to develop the industries of the country; and of the influence which the eloquent writings of Buffon had upon him. Desmarest was struck by the correspondence between the opposite cliffs of France and England which had already been pointed out by Guettard, and still earlier by Verstegan. Supporting by biological evidence the idea thus suggested, Desmarest arrived at the conclusion that the channel which now separated them had been cut by the currents of the sea.

His official duties necessitated much travel, but in the intervals of leisure he revisited and more closely examined localities which suggested subjects for further research. In this way he was led to study the origin of basalt, which had been a fruitful theme of controversy for many a long year. He noticed the prismatic structure of the basalts of Auvergne, and recognised them as ancient lavas, and, from descriptions of the general appearance of the columnar rocks of the Giant's Causeway, and an examination of hand specimens, he inferred that they were the same.

He explained the origin of valleys by referring them to the action of the streams which flow in them. This view had evidently been present to the mind of Avicenna, who in the tenth century maintained that mountains were made to stand out by the excavation of the valleys between them, while our great naturalist Ray dwelt upon the operation of streams in the degradation of the land, pointing out that the land must necessarily be eventually reduced below sea level by such agencies.

We are told how from an examination of volcanic phenomena, and in the attempt to correlate them, Desmarest was led to generalise upon the relation of the volcanic to the sedimentary rocks. He also constructed a map which, however, was not published till after his death. He has left many published works which attest his power, his accuracy of observation, and his judgment.

We have, then, an interesting account of the circumstances which led to the systematic exploration of Russia and the part played in it by Pallas, who, among other important observations, clearly recognised a geological sequence in passing from the centre to the outside of a mountain chain.

The rise of the modern spirit of mountaineering is dated from the time of de Saussure, who described so well the geological structure of the Alps, and whose sections of violently folded rocks anticipated so much of the recent work on that region, and whose experiments on the reduction of granite and basalt to a glassy rock by fusion and rapid cooling marked the commencement of experimental geology.

Our author then traces the development of the doctrine of the geological sequence of rocks as distinguished by their lithological character, towards which much had already been done, especially by the Wernerian school, and also the order of their formation as indicated by the succession of organic life buried in or associated with them, and differing in character at different periods of the world's history. The controversy as to the true nature of fossils, which has been referred to above, shows that importance had long been attached to them as a means of interpreting the history of the earth.

We have in the third lecture an account of Werner, the eponymous hero of a theory and a time. The great controversy between the Neptunists and the Vulcanists set men to search for facts in support of their respective views; and though a wrong working hypothesis may often have coloured the vision and warped the judgment, still the indications offered helped other less prejudiced men along lines where inquiry was fruitful. The Wernerian saw basalts interstratified with fossiliferous rocks, and apparently forming one member of a fossiliferous series, while others traced lava-flows with columnar structure from the crater to the sea, and saw how they might rest on ancient sediments and be themselves covered by newer deposits. Werner was wrong about his basalt, but he had introduced a greater care in investigation and a greater precision of description, and, above all, had so insisted upon the doctrine of geological succession that he placed geology upon a sounder basis than it had hitherto ever occupied.

Von Buch did much to free the scientific world from the tyranny of an uncompromising Neptunism by his demonstration of the constant occurrence of earth-movements down to quite recent times, as well as by many other independent researches recorded in numerous memoirs, and embodied in a large geological map of Germany.

If we give de Saussure credit for originating experimental geology, we must give Hutton a foremost place among those who insisted upon the importance of observation in the field. He was a man of wide interests and varied attainments. He realised the importance of Geology to Agriculture, and published works on "The Principles of Knowledge" and "The Progress of Reason from Sense to Science and Philosophy," this last title reminding us of Agostino Scilla's "La vana Speculazione disingannata dal Senso." The aims of both writers were the same, though Hutton got nearer the mark than his predecessor. In tracing the history of an idea, how often we find that the man who gave it to the world, in what we may call an available form, was not the man with whom it really originated. Take, for instance, the view that the action of heat in fusing material is directly influenced by the amount of pressure to which the body is subjected. This is quoted now with references to Sir James Hall, to Fairbairn and Hopkins, and others. But it was one of Hutton's fundamental doctrines, and Hutton got it from his friend Dr. Black, a sound chemist and shrewd experimentalist.

Hutton's first principle was that "no powers are to be employed that are not natural to the globe, no action to be admitted of except those of which we know the principle, and no extraordinary events to be alleged in order to explain a common appearance."

There are many men of note in our day who, going with the swing of the pendulum, as it were, believe in the greater intensity of the operations of nature in past ages, and still within the periods of which we have records in the sedimentary rocks. The phenomena which suggest this view may be reconciled to the strictest uniformitarianism by the doctrine that local catastrophic action is not inconsistent with continuity of causation.

Several distinguished French geologists, about the end of the last and the beginning of the present century, insisted upon the doctrine of stratigraphical sequence as fundamental, and this was soon found to involve the opinion that there was a definite order of succession among organic remains also. In England, while Giraud Soulavie was still a child, and before Cuvier or Brongniart were born, John Michell, Woodwardian Professor of Geology in the University of Cambridge, gave a clear account of the stratified arrangement of the rocks of England, and by his illustrations showed that he understood the principles of geological structure. "Let a number of leaves of paper," said he, "of several different sorts or colours, be pasted upon one another; then, bending them up into a ridge in the middle, conceive them to be reduced again to a level surface, by a plane so passing through them as to cut off all the part that has been raised. Let the middle row be again raised a little, and this will be a good general representation of most, if not all, large tracts of mountainous countries, together with the parts adjacent, throughout the whole world. From this formation of the earth it will follow that we ought to meet with the same kinds of earths, stones and minerals, appearing at the surface in long narrow slips, and lying parallel to the greatest rise of any long ridge of mountains; and so, in fact, we find them."

Then came William Smith, who based all his classifications on the "strata identified by their organic fossils." Sedgwick, who in early life had been the companion of Smith in some of his excursions in the north of England, was so impressed by the importance of the methods of geological research employed by Smith, that he spoke of him on one occasion before the Geological Society as "the Father of English Geology."

The next and last lecture brings us down to recent times, and the men whom many of us knew. In it we are told of the establishment of the Cambrian, Silurian and Devonian systems by Sedgwick and Murchison; of the discovery that glacial ice once gathered on the mountains of the British Isles; of the coordination of the wisdom of many observers by Lyell and Darwin in the enunciation of the great laws which guide the development of the organic and inorganic world; of the practical application by Nicol and Sorby of chemical and microscopic analysis to the identification of the minerals which make up the rocks, and often to the detection of their mode of aggregation.

The old controversy between Sedgwick and Murchison is introduced with a very skilful relative depreciation of Sedgwick; but perhaps the last has not been heard of that question, and it may yet be acknowledged that whereas the Arenig, Bala, and May Hill series were first clearly defined by Sedgwick, and placed in their true relative positions ("Life and Letters of Sedgwick," vol. i. 529-531; vol. ii. 510-563), the Llandeilo and Caradoc series were placed in their wrong order, and had the wrong fossils assigned to them in the "Silurian System" of Murchison, while the May Hill series was then unrecognised by him. Sir Archibald Geikie very fairly says that the middle disputed series must be either Upper Cambrian or Lower Silurian, and is unwilling to admit the new term Ordovician proposed for it.

Geologists owe a debt of gratitude to Mrs. George Huntington Williams, who founded the lectureship in memory of her distinguished and much lamented husband, the late Professor of Geology in the Johns Hopkins University. They will also accord their thanks to those who selected the first lecturer, and to him for his choice of a subject.

T. MCKENNY HUGHES.

THE TWO BONDS.

Memorials of William Cranch Bond and George Phillips Bond. By Edward S. Holden. Pp. 296. (New York: Lemcke and Buechner, 1897.)

IN these days when one is rather inclined to forget who were the pioneers of astronomy in different countries, it is interesting to be able to obtain a volume in which are described the lives, the difficulties to be surmounted, and the success attained by those who have been in these critical positions. The two Bonds—William Cranch and George Phillips, father and son—may be regarded as the first important contributors towards the early history of astronomy in America; and as they were the first two directors of the now well-famed Harvard College Observatory, the earliest founded of any college observatory in the United States, an account of their lives and work is very welcome.

The present volume purposes to afford such information, and Prof. E. S. Holden, and those who have helped him, deserve great credit for this valuable contribution to the history of astronomers. Prof. Holden, as he tells us, became acquainted with the Bonds in his youth, and in the preface he speaks of the unfailing kindness which he and his young friends received at their hands when at the observatory. "It has been my fortune," he says, "as an observer, to repeat some parts of his (George Bond's) work, and to obtain in this way an even more accurate judgment of his persistent thoroughness."

William Cranch Bond's father was a true Cornishman, and it is said that the family never ceased to regret their immigration to America. "A loyal love of England was characteristic of the family for many years. In household customs, manners and traditions they were thoroughly English down to very recent days."

William at an early age turned his attention to astronomy, and when only fifteen years old (1804) constructed an excellent chronometer, and also a quadrant which proved a very serviceable instrument. His taste for mechanical contrivances was considerable, and, as is now well known, he became very distinguished in this direction. Much interesting information is brought together in this volume, which shows that William Bond's career was by no means a smooth one, although it was rewarded with great success. The chronograph, now an important adjunct to meridional work, we owe to his mechanical ingenuity, and it is interesting to note that he was the first American to be elected a Foreign Associate of the Royal Astronomical Society.

William's son, George Phillips, was perhaps even more remarkable than his father in the amount of work which he accomplished. His *Magnum opus* on the great comet of Donati is perhaps the best known of his contributions, but there are others which were of nearly equal importance. It may be mentioned here that he was awarded the gold medal of the Royal Astronomical Society for the splendid memoir just referred to, but the official notification of the award reached America some days after his death. The nebula of Orion was minutely examined by him in the winters of 1857-8-9, in order to check the drawing made by his father, and investigate the truth of the remarks of Otto Struve, who criticised the positions of the stars in the engraving. This memoir is also of considerable importance, and illustrates the thoroughness which he displayed in his observational work. George Bond's forecast of the future of photography in its application to celestial physics has shown that he thoroughly understood the whole question, and, as Prof. Holden remarks, "he is the father of celestial photography."

The volume before us contains several interesting extracts from the diaries of George Bond, which include many important facts about his life. The extracts from his notes, made during two visits to Europe in 1851 and 1863, will be found very pleasant reading, as Bond visited most of the important observatories on this side of the Atlantic. His interviews with and descriptions of the astronomers of that day abound with interesting matter. In an account of his visit to Paris, he says about Leverrier:

> "In the frankness of his manners, in the absence of all *assumed* dignity, and in other points of resemblance, he is not unlike Mr. Adams. His straightforward way of expressing himself, and absence of all ostentation, render him what I should call accessible."

These diaries are followed by a collection of George Bond's correspondence, while the last chapter is devoted to an account of the scientific work accomplished by both the father and son. A useful appendix is added containing a list of the scientific writings of the two Bonds, compiled by Mrs. Richard F. Bond.

We cannot bring this notice to a conclusion without referring to the admirable way in which the lives and work of these two men have been set forth, and to the excellent reproductions of those celestial objects which will always be connected with their name, namely, Donati's Comet and the Nebula of Orion.

WILLIAM J. S. LOCKYER.

OUR BOOK SHELF.

Hints to Teachers and Students on the Choice of Geographical Books for Reference and Reading; with Classified Lists. By Hugh Robert Mill, D.Sc., F.R.S.E. Pp. 142. (London: Longmans, Green, and Co., 1897.)

A BIBLIOGRAPHY is always a difficult work to compile satisfactorily, and it becomes an even more delicate undertaking when an eclectic method is followed. The "Bibliotheca Geographica," which Herr Otto Baschin edits for the Berlin Gesellschaft für Erdkunde, is an example of the comprehensive type of bibliography, and Dr. Mill's little book admirably represents the type which aims at being serviceable rather than complete. Of the direct value of the book to teachers of geography, and indirectly to the science of geography, there can be no question: what surprises us is that Dr. Mill should have had the temerity to prepare it. Few people care to publish lists of what they consider to be the best books on any particular subject; and those who do commit themselves are often afterwards visited with mild regret. The author of this book, however, occupies an exceptional position for knowing what geographical works are in existence, and his lists of books show that he has made his selections carefully and with a mind free from prejudice. The volumes are classified under seventeen different headings, and dealt with in as many sections. A chapter on the principles of geography forms a suitable introduction to the more practical part of the work

But a list of books, even when annotated, is not a sufficient guide to a teacher, and it needs to be supplemented by a few remarks upon the general utility and educational value of the works mentioned. We are glad, therefore, that Dr. Mill precedes each list with a brief description of the particular branch of geography, or the continent, to which the books refer, and with hints on the use of the books. From the notes and the lists it is easy to learn what volumes are best to read, and where to turn for trustworthy information upon any geographical subject met with in ordinary life. The student may refer to the book with confidence, and the teacher of geography will benefit by taking it as his guide.

We notice that the volume was prepared at the request of the Geographical Association. The Association could find no better way to further its objects than by encouraging the publication of works of this character.

Sleep: its Physiology, Pathology, Hygiene and Psychology. By Marie de Manacéïne. Pp. vii + 341. (London: Walter Scott, Ltd., 1897.)

THIS book is divided into four chapters dealing with the subdivisions of the title. A good account is given of the phenomena and theories of sleep. The chief abnormalities are well described, and the author includes an account of certain allied conditions, such as double consciousness and Latah. The references to general pathology in this section are apt to be somewhat antiquated, as when the mental enfeeblement of goître is ascribed to withdrawal of blood from the brain. The subject of hygiene of sleep is evidently that to which the special work of the author has been devoted. She lays great stress on the proper management of sleep, and has somewhat novel views on the evils of prolonged sleep, and of fixed hours for sleep, and on the harmfulness of rocking babies in order to make them sleep. She describes very fully a condition which she terms the hypnagogic or half-awakened state, a condition characterised by increased suggestibility which is regarded as having an unfavourable influence on the mind if allowed to become well developed.

The chapter on psychology is devoted chiefly to dreams, of which a good systematic account is given, without anything especially new. The author seems to regard dreaming as an indication of high mental development; "dreams increase with the variety and activity of mental life," because intellectual workers dream more than servant girls. May this not be due to the fact that servant girls are usually the sounder sleepers?

Lessons from Life, Animal and Human. With an Introduction by Rev. Hugh Macmillan, LL.D. Pp. xvi + 529. (London: Elliot Stock, 1897).

THIS book is intended for preachers and Sunday-school teachers, and the lessons which it draws are not inferences but moral analogies. Thus an account of the bower bird establishes the maxim that "the relief times of life secure bodily and mental energy, and good spirits." The advertisements at the end of the book inform us that there are several volumes on the same plan, and that they have a good sale. The one before us is a compilation from many authors, with Darwin at one end of the scale and a crowd of obscure or anonymous writers at the other. The author is not particular in his choice of materials. He draws lessons from the most unlikely stories, and his familiarity with the literature of natural history can be estimated by the fact that he attributes to George Shaw the delightful account by Gilbert White of the behaviour of Timothy, his tortoise, in a shower of rain. The illustration or epigram from nature, which is so attractive in Shakespeare and other great writers, is here reduced to a "sad, mechanic exercise." When the allusions and emblems are arranged in cyclopædias, so that the preacher has only to look up a virtue or a vice in the index to find a more or less appropriate analogy, it is plain that the didactic anecdote is now "hackneyed and worn to the last flimsy thread."

L. C. M.

All about Animals, for Old and Young. Oblong 4to. (London: George Newnes, Ltd., 1897.)

ALTHOUGH the title is somewhat pretentious, this collection of large size photogravures is an enormous advance on the old-fashioned animal picture-books; and the volume forms an attractive Christmas gift for young people interested in natural history. All the plates are good, and some are excellent, although a few suffer from over-enlargement. A naturalist will, however, notice that one plate of deer is wrongly named; and a few emendations might here and there be suggested in the explanatory letter-press. This is for the most part well and brightly written, and serves to enhance the interest of the figures. In the first half of the book the greater number of the illustrations are from photos by Mr. Gambier Bolton, but in the second half other artists' names appear. And many of these latter are merely repetitions of the animals figured in the first half. This is decidedly a pity, as many other species might have been introduced. In a future edition these replicas might be replaced by others; and a rearrangement of the whole series in some sort of order would also be advisable. Even as it stands the book ought to, and doubtless will, command a large sale.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

Transpiration into a Space Saturated with Water.

For some time past[1] I have been endeavouring to decide whether the energy used in raising the water of the transpiration current is derived solely and directly from the inflow of heat at the evaporating surfaces of the leaf-cells, or whether stored energy (*i.e.* vital force) is in any way responsible for work done.

It has been observed that plants transpire into a space saturated with moisture. But I am not aware that it has been pointed out that this transpiration will continue even when no light falls on the leaves. Without this precaution we cannot assume that the space is really saturated at the surface of the leaves; for they will convert some of the light into heat, and so lower the state of saturation at their surfaces.

In my experiments small leafy branches were cut and set in a watery solution of eosin under a glass receiver. Beside the vessel containing the eosin, and under the receiver, a beaker filled with boiling water was placed. The receiver became immediately filled with water vapour, and, as the space was continually falling in temperature, owing to the cooling of the beaker, it remained always in a state of saturation. These arrangements were made in a feeble light, and then the receiver branch and all were set in total darkness. It is to be mentioned that a wet board cut off the direct radiation of the beaker from the branch. After an hour it was found that the eosin had risen into the leaves of the branch. In order to ensure that this rising was not due to reduced air pressure, previously obtaining in the water conduits of the branch, experiments were made in which any reduced pressure was equalised by setting the branch for one hour standing in water under the receiver, before setting it in eosin. The same result was obtained in these cases.

The raising of the eosin in this experiment seems probably due to a pumping action in the cells of the leaf, depending upon vital processes taking place there. This surmise is confirmed by the fact that the elevation of the eosin does not take place in a saturated atmosphere if the leaves have been killed. This may be proved either by leaves killed by immersion in water at about 90° C., or by exposure to chloroform vapour.

If the pumping action be a "vital" process we would expect it to be dependent upon a supply of oxygen, like growth and geotropic curvatures, &c. We, in fact, find this to be the case. Thus a branch wholly surrounded by water will draw up eosin from a vessel below, if exposed to light. The raising of the eosin will be but little if the light be cut off from the submerged branch. The action of light supplies the leaves with oxygen set free by assimilation; in the dark, however, the leaves can only obtain the small amount of oxygen dissolved in the water, and perhaps a little, too, derived by intramolecular respiration. With this limited supply the elevation of the eosin is inconspicuous.

The oxidising processes taking place in the leaf-cells must bring about some minute rise in temperature. This will, of course, favour evaporation. But I think this effect would be far too small to account for the whole phenomenon of transpiration into saturated spaces, as I have here described it.

That a very considerable amount of the pumping action is located in the leaves, may be shown by employing large leaves set upright in the eosin. It will be found that in a dark saturated space the veins of such large leaves severed from the stem will quickly become injected with the colouring fluid.

Henry H. Dixon.

Trinity College, Dublin, December 14.

The Zeeman Effect Photographed.

In the number of Nature issued on September 2, 1897, a short account is given (p. 420) of the recent work which has been done in the study of "the radiation of light in the magnetic field," and it is there remarked that it would be very desirable if the effects described by Prof. Zeeman were reproduced by photography. This, indeed, appeared to be all the more necessary in consequence of the doubts expressed and entertained as to whether the effect was a simple broadening of the spectral lines, or the production of doublets and triplets, or a combination of both effects. I accordingly availed myself of the opportunity afforded me, through the courtesy of the Royal University, of using for this purpose the splendid Rowland's concave grating mounted in the Physical Laboratory at Earlsfort Terrace, Dublin.

After the usual amount of preliminary difficulties and failures, I have finally succeeded in actually photographing all the appearances described by Prof. Zeeman, and I herewith enclose three small negatives which show the general character of the phenomena, and verify Zeeman's observations.

I do not now propose to enter into any particulars as to measurements, &c., so I shall merely describe the photographs.

The line represented is the violet line of cadmium which lies nearest to the blue, its wave-length being 4678. Plate A is taken with the slit viewing the spark *across* the lines of force of the magnetic field. The electro-magnet being excited, we have the triplet marked 1. The current was then turned off, and 2 was taken, which shows the line in its normal condition. A nicol was then inserted between the lens and the slit, and 3, 4, 5 were taken. Of these 4 shows the line when the magnet is not excited, while 3 and 5 were taken with the magnet excited. The position of the nicol in 5 was at right angles to that in 3, and as in 5 the side lines of the triplet have disappeared, it is proved that they are plane polarised. A faint middle line is shown in 3, but in my other photographs this line of the triplet is very weak, showing that it is mainly plane polarised in a plane at right angles to that of the side lines of the triplet. This is shown more distinctly in plate B, where 6 and 8 were taken with the excited field and the nicol interposed, the position of the nicol in 8 being at right angles to that in 6. The line marked 7 was taken with the magnet unexcited.

The third plate, C, was taken with the slit viewing the spark *along* the lines of force in the usual way through an axial aperture in one of the pole-pieces. In this plate the line marked 9 was taken with the magnet unexcited, whereas 10 was taken with the field excited. The latter is a distinct doublet, and a photograph which I took to-day with a quarter wave-plate and a nicol interposed, shows that the lines of the doublet are circularly polarised in opposite senses.

I wish to thank Dr. W. E. Adeney, the curator of the University laboratories, by whom the grating was mounted, for all the trouble he took to facilitate my work, and also Prof. Barrett, of the Royal College of Science, who kindly lent me his electro-magnet.

Thomas Preston.

P.S.—You will observe that all the effects described above are clearly visible on the plates (which I have forwarded) by aid of any ordinary magnifying glass. They lend themselves admirably to lantern projection, and when thrown on a screen the effects may be shown to a large audience. It is to be clearly understood, however, that the description above applies to this particular line (it is also true for other particular lines); but it is not implied that the same effect precisely is produced in every other line, either of the same or of different substances.

I am making further observations on this latter point, and hope to publish my results shortly.

T. Preston.

November 19.

[The negatives referred to by Mr. Preston show clearly the effects described, but they do not lend themselves to satisfactory reproduction, even when enlarged.—Ed. Nature.]

The Small Tortoiseshell Butterfly in December.

I see in more than one daily paper of this morning's date a paragraph announcing the appearance of a small tortoiseshell butterfly in Highgate Police Court yesterday as something unusual.

This butterfly is more or less common wherever nettles grow freely, and there is a succession of broods throughout the fine season, the last of which hibernates and reappears early in spring (in mild winters in the southern counties as early as February, or perhaps occasionally even in January). It is easily disturbed in its winter quarters, so there is really nothing surprising about its appearance now. The small tortoiseshell is usually one of the latest butterflies to retire from notice in autumn, and one of the first to reappear in spring.

Chiswick, December 21.

W. F. Kirby.

NYASA-LAND.[1]

SIR HARRY JOHNSTON has had a unique opportunity, and he has made the most of it. Most areas in Africa over which European protectorates have been established during the past twenty years are vast in size, varied in population, as a rule unhealthy in climate, and commercially unprofitable. In the Congo Free State, Rhodesia, British East Africa, Damaraland, German East Africa and Erithrea, all the best efforts of the administration have been necessarily devoted to a struggle against almost insuperable difficulties. In these cases the leaven of European yeast is so small in proportion to the vast bulk of African meal, that one part of the mass has begun to putrefy before the rest has lightened.

It fell, however, to Sir H. H. Johnston's lot to administer a district of exceptional promise, in which a group of Scotch planters and missionaries had been settled for many years. He found a number of men willing to help, and already possessing a considerable knowledge of the country and people. The protectorate s comparatively small and compact; and yet it includes a varied series of soils and climates. Most of the district is—for tropical Africa—fairly healthy. The natives are all Bantu. The Administrator was well backed financially, and had the implicit confidence of the Foreign Office officials. Hence he had an opportunity for developing the country on experimental lines that might make it a model for the larger and more chaotic European protectorates. How far Sir H. H. Johnston has succeeded in this task is shown in the magnificent work which he has published at the end of his term of office in Nyasaland. That is, however, a political question, which need not therefore be considered here, and we may at once pass to the consideration of the section of the work of scientific interest. For Sir Harry Johnston is fortunately a man of culture and scientific tastes, which his position gave him opportunity to satisfy. Hence at the end of his term of office in Nyasaland he has been able to publish a monograph upon the country, describing its history, its climate, its people, fauna and flora. The Germans have made great progress with an elaborate monograph upon German East Africa; but that is the work of a large staff of officers, whereas Sir Harry Johnston's is a one-man book, based on the studies carried out by a busy official during the intervals of administrative worries.

FIG. 1.—Captain Sclater's road to Katunga in process of making.

The title of the work, "British Central Africa," is somewhat confusing, as the author uses the name in two different senses: on the title-page and maps it includes all the British territories between the Zambesi on the south, and German East Africa and the Congo Free State on the north. It was in this sense that the term was originally proposed, at a time when it was hoped that the Blantyre Highlands would have been the administrative centre for a vast British territory, which would have connected British East Africa with the British dominions south of the Zambesi. Sometimes in the book the name British Central Africa is used in its original sense, and sometimes only as a synonym of Nyasaland Protectorate; excluding the western five-sixths of the country, which in 1894 were transferred to the administration of the British South Africa Company. Thus on pp. 152–154 there is a summary of "the present method of administration of British Central Africa," in which only the Nyasaland Protectorate is considered. Any one who failed to recognise the double sense in which the author uses his title, might infer that no progress has been made in the administration of the vast territory to the west of Nyasaland. It would, perhaps, have been as well to have entitled the book the "Nyasaland Protectorate," for the monographic treatment, which is its main merit, is entirely limited to that area. The great western territories are often referred to; but so scanty is the treatment they receive, that the name of that hardworking administrator Major Forbes is not even mentioned.

The book opens with a series of graphic descriptions of the various types of country included in British Central Africa, using the term in its wider sense. The author vividly depicts the beauties of the jungle-bordered rivers, of the scrub-covered foot hills, of the cypress forests near the mountain summits, of the meadowland on the high plateau, of the rough, craggy, granite kopjes, and of the squall-tossed lake. Included among the word pictures of these beautiful scenes is a graphic sketch of the death-bed of a mining prospector, which would not be out of place in a religious tract.

The second chapter gives a short account of the physical geography of the country, accompanied by three admirable maps and a series of excellent illustrations. The political history follows. There is a brief summary from prehistoric times up to 1889. One interesting suggestion here advanced is that the ancestors of the existing Bantu inhabitants of Southern Africa first invaded the region south of Lake Chad about 2000 years ago—a conclusion based on the wide distribution of the native name for fowl. After 1889 the history naturally becomes more detailed, for then began Sir H. H.

---

[1] "British Central Africa. An Attempt to give some Account of a Portion of the Territories under British Influence North of the Zambesi." By Harry H. Johnston, K.C.B., F.Z.S., &c. 8vo. Pp. xix + 544, with 6 maps and 220 illustrations. (London: Methuen and Co., 1897.)

Johnston's connection with the settlement. Chapters follow on the slave trade and on the European settlers; future additions to the ranks of the latter are advised in an appendix that civilisation has reached a stage in the Shire Highlands which makes a dress suit more useful than a pith helmet. A special chapter is devoted to the missionaries, to whom the country owes much; the debt is fully acknowledged, but the missionaries are reproached for the cant and the inaccurate reports written to "gammon" the British public.

The last four chapters of the book deal with the natural history. The botanical section includes a valuable list of Nyasaland plants compiled by Mr. J. H. Burkill. The first collections were made by Sir John Kirk in 1861 and 1862; and judging from the frequent repetition of the names of collectors in the catalogue, the three principal subsequent contributors have been Prof. G. F. Scott-Elliot and Messrs. J. Buchanan and A. Whyte. The general chapter on the flora calls attention to the most conspicuous and interesting plants; the remark of most general interest in this section is the author's repeated protest against Dr. Russel Wallace's well-known view that the tropics have less gorgeous displays of bloom than temperate regions, an impression, Sir Harry Johnston remarks, "formed from an exclusive acquaintance with the dense forests of Tropical America and Malaya."

The zoological chapter consists of lists of the animals, most of which have been determined by the staff of the zoological department of the Natural History Museum, with general notes by Sir Harry Johnston. The lists of insects are relatively the shortest, but the author confesses to "a sweeping hatred of the insect race" "It is surprising, to my thinking," he remarks, "that our asylums are not mainly filled with entomologists driven to *dementia* by the study of this horrible class." He says he cannot call to mind "one insect that is of any benefit to man . . . with the doubtful exception of the bees and the Cochineal Aphis," ignoring, therefore, the scavenging function of the flies, the chemical and medicinal products of the galls, the silkworm, and other such invaluable servants of man. The author appears most interested in the mammals, among his notes on which some original suggestions are made. With the author's usual courage, he runs a tilt against zoological nomenclature; he objects to Burchell's zebra being regarded as the type of the species "merely because it was the first one to be discovered"; and then renames the species *Equus tigrinus*. The varieties *burchelli*, *chapmani*, and *granti* he regards as only varieties of *Equus tigrinus*; while the name *Equus crawshayi*, that of the Nyasaland zebra, is ignored altogether. Sir Harry Johnston's views on phylogeny are as much his own as his methods of nomenclature. He publishes (p. 310) a diagram showing "the origin and relationships of modern groups of Horned Ruminants." According to this novel diagram the giraffe, which is usually regarded as a descendant of *Sivatherium*, is represented as one of the offspring of the Chevrotains. The prongbuck, definitely included by the author among the antlered ruminants, is shown as a branch of the giraffe stem. All the antelopes, sheep, and goats and the musk-ox are derived from the Capricorns, a group which is again a direct descendant from the Tragulidæ or Chevrotains. Early in the work the author tells us that our views on the relations of African mammals may be at any time "upset by unlooked-for discoveries," and too late in the day illustrates this view by referring to *Nesopithecus* (*sic*), a discovery which he describes as of "the most extraordinary importance and interest," apparently unacquainted with the recent literature of the subject.

The last section of the monograph describes the people, and here the author speaks as an expert as well as an enthusiast. The section includes a most valuable series of vocabularies, and detailed descriptions of the people and their habits. Some of the descriptions, indeed, are probably too detailed; much is recorded, though half veiled in dog Latin, which might have been more appropriately relegated to the pages of a strictly anthropological journal, instead of being published in a work the rest of which is suitable for general circulation.

The author's eulogy of his colleagues, notably the present Commissioner Mr. Alfred Sharpe, and his tribute to the chivalrous courtesy with which the Portugese always behaved in their relations with him, are instances of the author's tact and fairness, and they illustrate the spirit in which the work is written. The book is in every way worthy of Sir Harry Johnston's industry and scientific attainments, and will remain the most enduring memorial of his seven years' work in the development of the most promising of our tropical African possessions. Moreover, the illustrations, two of which are here reproduced by the courtesy of the publishers, are probably the best ever issued in an English book on Africa.

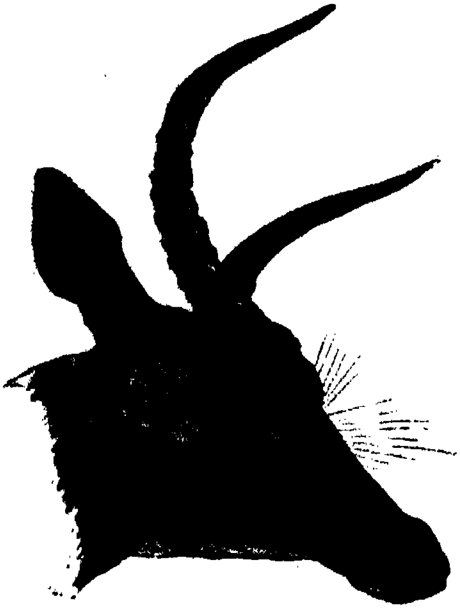

FIG. 2.—A Male Reedbuck's Head.

CHRISTMAS MUMMERS.

PROBABLY not a few readers of NATURE have, while staying over Christmas at a country house, been asked into the hall during the evening of Christmas Eve to witness a strange and fantastic rural performance called the mummers' play, and probably, too, they have promptly dismissed the whole thing as an idle and unmeaning piece of country folly. They would have noted, perhaps, the rude dialogue, the characters of St. George, the Prince of Paradine, and the King of Egypt; and they would have concluded that the performance was a faint echo of some miracle play of the Middle Ages, when the Church adopted this means of teaching the people.

Alike in the dismissal and in the uncareful noting of the characters, these observers of the country folk would have been wrong. The Christmas mumming play is worth attention, and more than mere casual attention.

Like other things which are done by the peasantry periodically, it is done by tradition, and traditional doings have a habit of getting weather-worn, so to speak. Some portions of them will remain fairly prominent, other portions will be more obscured; and so the proper sense of proportion among the different parts of the once perfect whole has disappeared. This is what has happened with the mumming play. St. George and his Eastern companions have remained in undue prominence with reference to other characters, and hence it has come about that the really archaic character of these plays has been lost sight of.

I need not describe the performance. Versions have been printed in the *Transactions* of the Folk-lore Society, and they have been examined scientifically by Mr. Fairman Ordish; but I will try briefly to explain the origin of these mimic representations of forgotten things.

The first thing to observe about the play is that the dialogue is in a state of decay. To restore it to anything like its earlier form would require the careful collation of all the versions with a view of ascertaining the portions that are practically common to all, the portions that are common to only a few variants, and the portions that are unique. This operation needs extension, too, beyond the mere mummers' play, for there are the Pace Egg play, the sword dance, and the Plough Monday play, which have most of the characteristic features of the mummers' play, and cannot but be products of the same original. After the dialogue is duly examined, there is the action of the play to consider. It is remarkable that all the actors in the different parts of the country from North England to Cornwall, however widely they differ in their dialogue and in the names of their characters, differ very little, if at all, in their action. The chief features of this action are found to be (1) the drawing of a circle with a broom for the place in which the play is to be performed; (2) the fight, in which the swords are very carefully locked together round the neck; (3) the death and revivification of the champions; (4) the costume of the characters, partly made of paper to imitate armour, as some writers have thought, but leaves of trees, as I think I shall be able to prove, and partly in imitation of animal characters.

Now in this traditional form of acting and of dressing there is more of archaic survival than in the dialogue part of the play. The circle which is formed for the players to act in is meaningless, unless it be interpreted as a magic ring drawn or constructed by the broom—that is the magic weapon of the witch, about which Prof. Karl Pearson has recently written so ably. The invariable position of the sword leads us to its parallel in the sword dance of the north of England, and hence to innumerable links with Scandinavian ritual. The death and revivification of the warriors is the reproduction of that eternal contest between winter and spring, which is to be found throughout the agricultural ceremonials of the European people, and which Mr. Frazer has examined so thoroughly. The costume of the players, some examples of which, thanks to Mr. Fairman Ordish, are to be found in the Anthropological Museum at Cambridge, connects the characters with the ritual belonging to the tree and animal cults of an almost dateless past. And in the whole thing we have, I doubt not, one of those "manifold though never developed germs of dramatic representation" of which Grimm gives some interesting examples, and which he explains "can be traced up to the most antique festivities."

Let me shortly state the arguments in support of this view. The contest, the death, and the revivification, are the central factors which need explanation, and this can best be done by examining their accompaniments, the setting, so to speak, in which they are embedded. We first of all dismiss the period of Christmas as being the special period of these mumming plays. It has grown to be so now; but that this is a late growth is shown by the fact that the same play is to be found, performed under another name, the Pace Egg, at Easter, and that significant parts of the same play are to be found performed as the Plough Monday play of early spring time. This agrees with the rule of most of the surviving traditional festivals attached to particular periods or dates of the Christian calendar. They are at some places attached to one festival, in other places attached to another, and it seems certain that these ancient ceremonies were transferred to the Christian season most favourable locally to their continuance, but not necessarily the same period of the year as they were originally performed. Without then fixing upon any of the Christian festivals as the archaic season for the play taking place, we may leave the question of date open, to be settled by other considerations. The next important point is the costume. Examining this carefully from the very modern examples which are preserved, we may conclude that the use of paper is but the adaptation of the cheapest material to be got for the purpose required. Now the paper dress is formed by stitching together a series of small pieces in a sort of scaly fashion, and the only two suggestions to account for this are first scale armour, secondly leaves. Against the idea of scale armour being present in the minds of the rustic performers there is much to be said, and particularly that scale armour is not in accordance with the other conditions of the play. In favour of leaves being intended there are many examples, notably the Jack-in-the-Green of May Day, of such dresses being used in these popular dramas; and, further, there is the fact that some of the mummers, or maskers as the name implies, formerly disguised themselves as animals—goats, oxen, deer, foxes, and horses being represented at different places where details of the mumming play have been recorded. It seems, then, that we have as data for ascertaining the principal features of the mumming play: (1) the undoubted fact of animals being represented; (2) the deduction that trees were also represented; (3) a contest, which resulted in the death of one of the opponents; (4) the restoration of the dead to life. Now mimic representations of an archaic ceremony in which actors take the parts, both of animals and trees, are found all over Europe, and they take place at spring time, just when leaves have once more appeared after the desolation of winter. This association of facts in the spring-time festivals can be equated with the association of facts in the mumming plays with sufficient precision to make it safe to conclude that the equation is due to a descent from a common original.

What is that original? In the personages who are thus slain in mimicry, to adopt Mr. Frazer's language, it is impossible not to recognise representatives of the tree spirit, or spirit of vegetation, as he is supposed to manifest himself in spring. The object of slaying the spirit of vegetation at any time, and above all in spring, when his services are most wanted, is that the divine life, incarnate in a material and mortal body, should be conveyed from the old representative of the god to a new incarnation. The killing of the god is only a necessary step to his revival or resurrection in a better form. Students of Mr. Frazer's work will not need to be reminded of the details of this argument, but I point out that they explain adequately not only the leafy and animal dresses of the English mummers, but the death and revivification of the principal actors; and they find their most archaically developed form in the Norse mythic fight between Thok and Balder, in other words between winter and spring.

What then, it may be asked, is to become of St. George and his Eastern companions, if all, except these, have so great an antiquity? The answer is that they are the later engraftings, and the answer is fortunately one which can rather confidently be given. Folk-drama, like other branches of folk-lore, needs studying carefully and minutely to see what its chief essentials are. It is clear that the Church could not repress the dramatic representations of the people. So they utilised them. They turned characters belonging to the primitive religion into characters bearing the names of, and having just the slighest resemblance to, Christian characters. St. George was a knight who fought and slew enemies. He was fitted to do the fighting therefore in these old plays. But he did little else. He had to conform to traditional ways, if he introduced non-traditional speeches. He had to see his slain enemies restored to life, and he had to dress in the traditional manner and meet the traditional animal characters. Except, indeed, for the names of the characters there is nothing in these mumming plays really belonging to Christian knighthood and feudal nobility. No one would dream of attributing to them any of the dignity of romantic chivalry; they remain as they were originally, traditional representations of popular festivals. There is only the rudest action and the most archaic ideas: and it is not difficult, therefore, to get rid of the thin veneer of ecclesiastical influence in order to search for the more archaic relics underneath.

LAURENCE GOMME.

NOTES.

At a meeting on December 15, Sir W. H. Flower, K.C.B., F.R.S., was elected an Associate of the Royal Academy of Sciences of Belgium.

PROF. G. CAREY FOSTER, F.R.S., will resign the Quain Professorship of Physics, University College, London, at the close of the present session.

DR. AUGUSTUS D. WALLER, F.R.S., Fullerian Professor of Physiology and Comparative Anatomy at the Royal Institution, has resigned his chair.

It is with deep regret that we announce the death of Prof. T. Jeffery Parker, F.R.S., professor of biology in the University of Otago. Though Prof. Parker died on November 7, the news has only just reached this country; and it is given melancholy interest by the fact that the "Text-Book of Zoology," upon which Prof. Parker had for some time been engaged with Prof. Haswell, was only completed a few days before his death.

THE Council of the Chemical Society have recommended the following as Foreign Members to be balloted for at the next meeting, January 20:—Prof. Remsen, Baltimore, U.S.A.; Prof. Troost, Paris; Prof. Moissan, Paris; Prof. Raoult, Grenoble; Prof. Ostwald, Leipzig; Prof. Curtius, Bonn; Prof. Mensutkin, St. Petersburg; Prof. Markownikow, St. Petersburg; Prof. Arrhenius, Stockholm; Prof. Waage, Christiania; Prof. Franchimont, Leyden; Prof. van der Waals, Amsterdam; Prof. Spring, Liége; Prof. Körner, Milan.

WE regret to learn that Prof. Francesco Brioschi, president of the R. Accademia dei Lincei, died at Milan on December 13.

THE *Athenæum* announces that the mineralogist Dr. Albrecht Schrauf, author of several scientific works—among others of a "Lehrbuch der physikalischen Mineralogie," of a "Handbuch der Edelsteinkunde," and of an "Atlas der Krystallformen,"—has just died at Vienna in his sixtieth year. Dr. Schrauf was professor of mineralogy at the University of that place, and director of the Mineralogical Museum.

THE death is announced, at Cape Colony, of Prof. James Holm, late Professor of Physics at the South African College Cape Town. Prof. Holm (says the *Electrician*) was born in Argyllshire in 1869, and had a brilliant career at Glasgow University, passing on to Edinburgh. Subsequently he spent several sessions in private research, under the special direction of Lord Kelvin, in the physical laboratory of the Glasgow University, and also in the electrical engineering workshops. At the completion of his scholarship he was appointed Demonstrator in Physics at the University College, Nottingham, where he remained until appointed to a professorship at the South African College in 1895.

MR. H. F. DONALDSON, Engineer-in-Chief of the London and India Docks, has been appointed Deputy Director-General of the Ordnance Factories.

THE sub-tropical Botanical Laboratory at Eustis, Florida, has been abandoned, and the work transferred to the Division of Vegetable Physiology and Pathology of the Department of Agriculture, Washington.

MR. A. C. HARMSWORTH has presented his Arctic ship *Windward* to Lieutenant Peary, and will have her overhauled and sent to America for his use in his coming Arctic expedition. This generous act is the latest incident in that series which has shown that England and America are bound by the strongest brotherly ties in their mutual interest in Arctic work.

PROF. OLIVER LODGE will commence his course of six lectures (adapted to a juvenile auditory) upon "The Principles of the Electric Telegraph," at the Royal Institution on Tuesday next, December 28. The subjects of the individual lectures are:—The production of an electric current; detection of an electric current; land telegraphy; ocean telegraphy; principles of wire and cable signalling; space telegraphy.

CHRISTMAS lectures for juveniles are increasing in favour. At University College, Liverpool, Prof. Herdman, F.R.S., will give a course of three lectures and a museum demonstration, on some of the more attractive parts of natural history, during the Christmas holidays. The announcement states that the course is for boys and girls, for whom the best places will be kept; adults will only be admitted on sufferance, should there be room for them.

THE following are among the papers announced for reading at the meetings of the Society of Arts after Christmas, in January and February:—"The Projection of Luminous Objects through Space," by Mr. Eric H. S. Bruce; "Fireproof Construction of Domestic Buildings," by Mr. Thomas Potter; "The Cinematograph," by M. Jules Fuerst.

THE will of the late Dr. George H. Horn (says *Science*) gives his valuable entomological collections, together with his entomological books and instruments and an endowment of 200 dols. per annum, to the American Entomological Society. From the residuary estate, after the death of his sister, the Entomological Society is to receive 5000 dols., the Philadelphia Academy of Natural Sciences 1000 dols., and the American Philosophical Society 500 dols.

AT the recent annual meeting of the Institution of Civil Engineers it was announced that, in respect of papers read during the Session 1896–97, the Council had made the following awards:—The Institution premium, value 10*l.*, to Mr. W. M. Mordey for his paper entitled "Dynamos"; the Paris Electrical Exhibition premium, value 5*l.*, to Mr. John Gavey for his paper on "The Telephone Trunk Line System in Great Britain"; the Fahie premium, value 5*l.*, to Mr. Benest for his paper on "Some Repairs to the South American Company's Cable off Cape Verde in 1893 and 1895." An extra premium of 5*l.* was awarded to Mr. A. P. Trotter for his paper on "The Disturbance of Submarine Cable Working by Electric Tramways." The Council have decided to increase the number and values of the annual premiums commencing with the Session 1897-98 The Willans premium, the value of which the Council have increased to 25*l.*, has been awarded to Mr. Mark Robinson (member) for his paper entitled "On the Recent Development of the Single-Acting High-Speed Engine for Central Station Work."

MR. G. E. BROWN writes upon a proposed memorial to Henry Fox Talbot, in the *British Journal of Photography*. All photographers are aware of the value of Fox Talbot's researches; in fact, modern photography would have no existence but for the labours of the inventor of the calotype process. Yet, as Mr. Brown points out, no mark of appreciation of his services has been made. At Bry-sur-Marne stands a monument to Daguerre; Chalons can show one to Nicephore Népce; but Lacock, in Wiltshire, the home of the Talbots, can display no sign of public gratitude. The memorial proposed is the restoration of the chancel of Lacock Church, where Fox Talbot's father and many of his ancestors, as far back as the sixteenth century, lie buried. It is probable that a more distinctly commemorative character may be given to some definite feature in the chancel, such as a window, but the whole chancel will be commemorative. Subscriptions are invited, and may be sent to the "Fox Talbot Memorial Fund," Capital and Counties Bank, Chippenham.

THE report of the Departmental Committee appointed by the Home Secretary to inquire into the testing of explosives for use in coal mines has just been issued as a Parliamentary paper. It is recommended that explosives be tested in a highly explosive mixture of coal gas and air only, and the Committee feel confident that any explosive which shows itself superior in this mixture would exhibit the same increase in safety in the presence of a coal dust mixture. Taking into account the general results of the experiments, the Committee have drawn up a test, and recommend that this should be applied to all explosives which are submitted for inclusion in the permitted list. The full details of this test are given in an appendix. The amount of the charge which it is proposed to fire will be the equivalent of 2 ozs. of dynamite and of 6 ozs. of gunpowder. In order to pass the test an explosive must not cause more than two failures in forty shots, a failure being defined as either an ignition of the gaseous mixture or an incomplete explosion. After most careful consideration it has been decided to recommend that the test be carried out with a stemming of nine inches of dry powdered clay of good quality well rammed over the charge.

THE Trustees of the British Museum have decided to discontinue the opening of the Exhibition Galleries on week-day evenings from 8 to 10 p.m. after the close of this year; and, instead, to keep them open until 6 p.m. all the year round. The evening opening commenced in February 1890, on the installation of the electric light; the galleries, however, being opened only in sections, as the electric plant is not powerful enough to light up the whole building. At first the eastern and the western portions of the Museum were opened on alternate week-day evenings; but the number of visitors so rapidly declined, that the galleries were afterwards further subdivided into three sections. The numbers, however, have still continued to decline. The experiment of evening opening, having thus had a fair and patient trial, will now be abandoned; and a lengthened exhibition by day will be substituted, during the months when the Museum has hitherto been closed at 4 p.m. or 5 p.m., according to the season of the year. On and after Monday, January 3, the Exhibition Galleries will be kept open throughout the year from 10 a.m. to 6 p.m. It is believed that the extension of time will be appreciated by visitors, particularly during the winter months, when hitherto the closing hour has been 4 p.m. The arrangements for opening on Sunday afternoons will not be altered; visitors being admitted at hours varying between 2 p.m. and 7 p.m., according to the season of the year.

THE severe gale of November 28 and 29, which caused such serious damage all along the south-east coast of this country, had the effect of raising the tide to an abnormal height, the tide of the following day being considerably depressed. Writing in the *Engineer*, Mr. W. H. Wheeler says the wind appears to have had the greatest effect in increasing the height of the tide along the part of the coast extending from the Humber to the east end of the English Channel. The wind on the previous days had been blowing strongly from the south-west, a condition favourable to increasing the height in the Channel; it then flew round to the north-west, a quarter which always raises the tide in the North Sea. The combined influence of the winds from these two opposite quarters would therefore tend to concentrate the full effect of the tide along the south-eastern coast, and the records of the damage done to the cliffs and in flooding, owing to the water breaking through or flowing over the banks, and doing other damage, show that this was the case. Fortunately the gale occurred five days after the new moon, or the effect would have been even more serious. The amounts by which the water at a few places rose above the proper tide-mark on Monday, November 29, are as follows:—Grimsby, 5 feet 11 inches; Hull, 5 feet 3 inches; The Wash (Boston Dock), 5 feet 3 inches; Lynn, 7 feet; Yarmouth, 8 feet; Ipswich, 6 feet 6 inches; Dover, 6 feet 1 inch; Gravesend, 3 feet 4 inches; Newhaven, 2 feet 4 inches; Portsmouth. 1 foot 8 inches.

THE last published *Annali* of the Italian Central Meteorological Office contains particulars of the activity of that department in various directions. One section deals specially with agricultural meteorology and the distribution of thunderstorms, and publishes a monthly review containing ten-day means for a considerable number of stations. A regular discussion of the mean weekly and annual frequency of thunderstorms and hail has been undertaken, and the results for some provinces have been laid before the Royal Academy. Another section deals specially with earthquakes, and the observations are regularly published in a monthly *Bulletin*. Dr. Agamennone, to whom we are indebted for many researches in this subject, has established a geodynamic observatory at Constantinople, with instruments similar to those in use at Rome. Considerable attention is paid to terrestrial magnetism, and the present volume contains an account of the absolute measurements of the different magnetic elements made in Italy in the years 1888-9. Among the purely meteorological discussions we may mention one on the anemometrical records at Vicenza for the fifteen years 1875-90. The author states that the diurnal velocity curve is far from showing the simplicity of a single diurnal wave.

THE properties of algebraic curves, classified on the basis of their gonality, have been studied by Prof. Amadeo, and a paper on the subject—the third of a series—is published in the *Rendiconto* of the Naples Academy (iii. 3a, 8-10). After dealing at length with the k-gonal curves of the first and second species, the author passes on to consider those of species s. The most noteworthy feature is the proof that a k-gonal curve of species s can be referred uniquely to a k-gonal curve of the first or second species, according as s is odd or even.

THE *Botanical Gazette* for November prints a very interesting history of the public gardens and plantations in Jamaica, contributed to the *Proceedings* of the Botanical Society of America by Mr. W. Fawcett, the Director. The first Botanic Garden in Jamaica was formed about 150 years ago by a private individual, Mr. Hinton East, on his property near the present village of Gordon Town, nine miles from Kingston. It was shortly afterwards taken over by the Government, and two gardens established, a "European" and a "Tropical." But it was only within about the last thirty years that a serious attempt was made, under Sir J. B. Grant, to make the Gardens of economic value to the Colony, during which time much has been done to determine what foreign importations are most suitable to the climate. There are now six larger or smaller Gardens, viz. the Parade, King's House, Hope, Hill, Castleton, and Bath Gardens, varying greatly in their climatal conditions. Mr. Fawcett estimates that the native flora of the island includes about 450 ferns, and 2180 species of flowering plants.

ATTENTION has been previously called in our columns to Prof. Felix Plateau's observations of the way in which flowers attract insects (*Bulletin de l'Académie Royale de Belgique*), from which he inferred that the presence or absence of brightly-coloured corollas possessed little or no influence on their insect visitors. These researches are concluded in the current number of the *Bulletin* (iii. 34). Repeated experiments on seventeen species of plants, all genuinely anemophilous, prove that it is sufficient to place on the greenish or brownish inconspicuous flowers some artificial nectar, represented by honey, in order to attract numerous insects. Moreover, it appears (both from the author's personal observations and from previous writings) that insect visits, often frequent, have been observed on ninety-one forms of entomophilous plants having flowers devoid of conspicuous colour, viz. forty-one with green, thirty-eight with greenish, and twelve with brown or brownish flowers. The author has verified the coloration for seventy-two of these plants, and has himself observed the visits of insects to sixty-three, or more than two-thirds of them. Prof. Plateau concludes that insects are little affected by the presence or absence of brilliantly coloured floral organs; what they seek is the pollen or nectar, and in finding these their sense of vision is merely accessory; while, on the other hand, they are guided with certainty by some other sense, which can only be that of smell.

AN important series of investigations has recently been published in the *Annales de l'Institut Pasteur*, by Dr. Paul Remlinger, on the artificial communication of typhoid fever by the alimentary tract. Hitherto it has been customary to infect animals with the typhoid bacillus by introducing this organism into the peritoneum, but in consequence of the attention which has lately been directed to the danger of typhoid being disseminated through the direct watering of vegetables with sewage, Dr. Remlinger experimented on the possibility of infecting rabbits and rats with typhoid by feeding them on vegetables soaked with typhoid bacilli. These experiments showed that it was possible to induce typhoid fever in rats and rabbits by this means, and Chantemesse has not only confirmed Remlinger's results, but states that he has succeeded in infecting monkeys with typhoid in a similar manner. The following experiment gives some idea of the results obtained by Remlinger in this interesting inquiry. A rabbit commenced to eat typhoid-soaked vegetables on August 30; two days later its temperature rose and later on it became thin and apathetic, and on September 7 the supply of typhoid bacilli was stopped; on September 15 symptoms of diarrhœa made their appearance, and blood taken from the animal gave a positive reaction with the sero-typhoid test; a few days later the temperature became normal, and the animal gradually recovered, but on September 30 its blood still gave a positive reaction with the above test. Experimental typhoid induced in this manner in rats resembled very closely the symptoms observed in the case of rabbits. It is, however, necessary in order successfully to infect animals with typhoid by this means, to make them frequently swallow large quantities of the bacilli.

THE number of *Isis* (Dresden) for the first half of 1897 contains a paper, by Dr. P. Menzel, on the "Tertiary Flora of the 'Jesuitengraben' at Kundratitz," a very rich layer, from which a number of new species are described. A plate accompanies the paper.

THE Report of the Director of the Botanical Survey of India for 1896–97 includes reports from all the Directors of Departments except that of Southern India. The results will shortly be dealt with of the botanical exploration, by Lieut. Pottinger, of a portion of the valley of the Irrawaddy, a country hitherto absolutely unknown. A synopsis is given of the flora of Western India as far as the Tiliaceæ.

THE Tuesday evening science lectures at the Royal Victoria Hall, Waterloo Road, during January, will be as follows:—January 4, "Coal," by Mr. W. F. Rudler; January 11, "Diamonds," by Prof. H. A. Miers, F.R.S.; January 18, "Through the New Gold Fields of Alaska to Bering Strait," by Mr. H. de Windt; January 25, "Mars as a World," by Mr. R. A. Gregory.

PHILIP'S revolving planisphere is well known to be a very handy and serviceable means for finding the constellations visible at any time. A more substantial form of the contrivance, with an adjustable calendar combined, has just been published by Messrs. George Philip and Son. The arrangement is made so that it will stand alone, or it may be hung from a wall. It is thus a suitable ornament for the astronomer's desk, or for the observatory.

THE additions to the Zoological Society's Gardens during the past week include a Mandrill (*Cynocephalus mormon*, ♂), a Mona Monkey (*Cercopithecus mona*, ♂), two Green Monkeys (*Cercopithecus callitrichus*, ♂ ♂), a —— Hawk Eagle (*Spizaetus* ——), seven African Walking Fish (*Periopthalmus koelreuteri*) from West Africa, presented by Dr. H. O. Forbes; a Sykess Monkey (*Cercopithecus albigularis*, ♂) from West Africa, pressented by Mr. Henry Curnow; a Binturong (*Arctictis binturong*) from Malacca, presented by Mr. W. W. Skeat; a Blotched Genet (*Genetta tigrina*) from South Africa, presented by Mr. J. E. Matcham; a Ruddy Ichneumon (*Herpestes smithi*) from India, presented by Colonel F. Morison; two Grey Struthideas (*Struthidia cinerea*) from Australia, presented by Mr. R. Phillipps; a Crimson-eared Waxbill (*Estrelda phœnicotis*) from West Africa, presented by Miss Aves; a Thar (*Capra jemlaica*, ♂) from the Himalayas, six White Pelicans (*Pelecanus onocrotalus*) from Egypt, deposited; three Coscoroba Swans (*Coscoroba candida*) from Antarctic America, a Macqueen's Bustard (*Houbra macqueeni*) from Western Asia, purchased.

OUR ASTRONOMICAL COLUMN.

NEW DOUBLE STARS.—The discovery of new double stars at the Royal Observatory, Cape of Good Hope, by Mr. R. T. A. Innes, is proceeding apace, and Dr. Gill publishes in *Astr. Nach.*, 3462, a fourth list of such objects. The number of stars given is twenty-nine, making the total now discovered 259. The distances of the components range in this last list from 0″·5 to 5″.

NEW VARIABLE STARS.—More than once in this column it has been shown that useful astronomical work can be done with instruments of only moderate size, backed up by steady observation; but no one has done more to emphasise this fact than Dr. Anderson, of Edinburgh, first with his discovery of Nova Aurigæ, and later by a close scrutiny of stars to detect any variability. From observations made with his 2½-inch refractor, he points out in *Astr. Nach.*, 3461, that a star in Aquila, not mentioned in the Bonn *Durchmusterung*, but whose position (possibly wrong to the extent of 1′) is R.A. 19h. 31m. 10s. Decl. + 11° 23′, has proved to be variable

Again, in *Astr. Nach.*, 3463, he gives notice of two new variables—probably of short period—B.D. + 67°·1124 in Draco, and B.D. + 30°·1329 in Gemini, with respective positions: R.A. 19h. 9m. 54s., Decl. + 67° 2′·4, and R.A. 6h. 37m. 50s., Decl. + 30° 25′.

All the positions are given for the epoch 1855.

VARIATIONS IN THE SPECTRUM OF NEBULA IN ORION.—Often has severe criticism put scientific facts on a firmer basis, and such might be said to be the case with Dr. Scheiner's doubts concerning Prof. Campbell's observed variations in the spectrum of different regions in the Orion nebula, made in 1893. To test the accuracy of some specific observations, Prof. Campbell has called in the assistance of three of his colleagues (Prof. Schaeberle amongst them), and, with the aid of the 36-inch refractor and an efficient spectroscope, different regions of the nebula have been examined to observe the behaviour of the three principal nebular lines.

The mode of making the observations was to use a coarse micrometer wire, occulting each of the lines in turn, so as to determine the relative brightness of the remaining two, when all three are observable.

The following are the results, which in the main all the observers are agreed upon:—Central part of nebula (Trapezium region): the three nebular lines all conspicuous, the line λ 5007 being the brightest, whilst the lines λ 4959 and λ 4861 are nearly of the same intensity as each other.

In the region surrounding the star Bond, No. 734, the line λ 4861 was the only one visible, the other two lines having disappeared; whilst in the region south-west of the Trapezium all three are visible, but the line λ 4861 is still the brightest.

No doubt photographs will be secured whilst Orion is well situated, and so further establish these observations made visually.

WINNECKE'S PERIODIC COMET.—One is reminded on reading the life-work of the late Dr. Winnecke, in the last number of NATURE, that had he lived a few weeks longer he would probably have seen another return of the periodic comet which bears his name, for it is due at perihelion on March 20, 1898, but of course will be better situated for observation some time before this. The elements and ephemeris as given by Mr. C. Hillebrand in *Astr. Nach.*, 3447, are as follows:—

Elements.

	26 October. 1897.	15 March, 1898.	
	° ′ ″	° ′ ″	
M =	325 24 26·7	359 3 52·0	
π =	274 14 33·3	274 14 39·0	1900
☊ =	100 53 34·3	100 53 11·5	1900
i =	16 59 34·4	16 59 33·8	1900
φ =	45 37 35·6	45 37 14·7	
μ =	608″·3483	608″·5559	

Ephemeris.

1897–98.	R.A. h. m. s.	Decl. ° ′	log r.	log Δ.	1 : r²Δ².

Feb. 3	17 31 41	−11 9·0	0·05738	0·15349	0·379

The best time for making a search will be early in the morning, shortly before sunrise, from about now till early in February. The comet is never visible to the naked eye, and will at first be faint with the aid of a telescope; its apparent path is in a south-easterly direction through Virgo, Libra, Scorpio, Sagittarius, and Capricorn.

KEKULÉ MEMORIAL LECTURE.

AT an extra meeting of the Chemical Society, held on Wednesday, December 15, Prof. F. R. Japp, F.R.S., delivered a memorial lecture in honour of the eminent German chemist, Friedrich August Kekulé, whose death occurred in July 1896. The lecturer said that Kekulé's supreme merit lay in his contributions to theoretical chemistry. His greatest achievements in this department were the doctrine of the linking of atoms in terms of their valency, and, growing out of this, the theory of the structure of organic molecules, both in open-chain and in closed-chain compounds. These were not recondite theories, hidden away in the depths of the science; they were organic chemistry itself, and were learnt by students on their first introduction to the subject. Kekulé acknowledged that his theories were based on Gerhardt's type theory, on Williamson's theory of polyvalent compound radicles and multiple types, and on Odling's theory of mixed types, which was a deduction from Williamson's theory. Less consciously, perhaps, his opinions were influenced by E. Frankland's theory of the valency of elementary atoms, and by Kolbe's speculations on the constitution of organic compounds. Kekulé developed these ideas, which he found scattered throughout the writings of his predecessors, added to them, and welded the whole into the coherent system which formed our present theory of the structure of organic compounds. In Kekulé's model of the carbon atom "the four units of affinity," to quote his own words, "radiate from the sphere representing the atom so that they end in the faces of a tetrahedron." This model was destined to play an important part in the development of theoretical chemistry; it was the foundation of stereochemistry. Kekulé's benzene theory was the crowning achievement, in his hands, of the doctrine of the linking of atoms; it was the most brilliant piece of scientific prediction to be found in the entire range of organic chemistry. What Kekulé wrote in 1865 had since been verified in every essential particular. Not only had the various substitution derivatives been discovered in the number and with the properties required by the theory, but various observations which appeared to contradict this theory had been proved erroneous. Moreover, the theory had shown itself to be capable of boundless development, and there seemed to be no limit to the fruitfulness of Kekulé's conception of closed chains or cycloids. The extensions of the idea, of which extensions Erlenmeyer's naphthalene formula and Dewar's formulæ for pyridine and quinoline were among the earliest instances, had gone on increasing in a rapid geometrical ratio, until, at the present day, the literature dealing with cycloids, although of so recent growth, was more than twice as voluminous as that of the paraffinoids. But even in the undeveloped state of the subject prior to Kekulé's theory, the facts were apparently so intricate and so unconnected that few chemists could claim to have mastered them. The theory appeared; the previously unmarshalled facts fell into their proper places; and not only this, but it was possible to say whether, in any given section of the subject, the facts were complete or only fragmentary. The debt which both chemical science and chemical industry owed to Kekulé's benzene theory was incalculable. As regards the former, three-fourths of modern organic chemistry was, directly or indirectly, the product of this theory; and as to the latter, the industries of the coal-tar colours and the artificial therapeutic agents, in their present form and extension, would be inconceivable without the inspiration and guidance of Kekulé's fertile idea. By the accuracy of his predictions he had done more to inspire a belief in the utility of legitimate hypotheses in chemistry, and had therefore done more for the deductive side of the science than almost any other investigator. His work stood pre-eminent as an example of the power of ideas.

RECENT RESEARCHES ON TERRESTRIAL MAGNETISM.[1]

II.

UP to this point we have regarded the system of magnetic forces in play upon the surface of the earth as constant. I have already hinted that this is not the case, and that the difficulties of our investigation are immensely increased by the fact that all the phenomena with which we deal are in a state of flux. Nothing is fixed from year to year, from day to day, from hour to hour. It is hardly too much to say that at times almost every minute brings with it changes which it is the business of the magnetician to investigate and explain. For the moment, however, I wish to fix attention only upon the secular change to which I have already referred. Not only does the angle which the magnet makes with the geographical meridian vary, but the dip also increases and diminishes in turn.

---

[1] The "Rede Lecture" delivered in the Senate House, Cambridge, on June 9, by Prof. A. W. Rücker, F.R.S. (Continued from p. 163.)

An interesting method of depicting these changes has lately been suggested by Dr. Bauer. He imagines the observer to be stationed at the central point of a magnet suspended so that it can turn freely in any direction. To a person thus situated, and capable of continuing his observations through periods far exceeding the range of human life, the north pole of the magnet would appear to describe a curve. It would move sometimes to the right, sometimes to the left, and would simultaneously rise or fall. The facts which have been observed during the last 150 years, and, in some places, for longer periods enable us to draw these curves. At the great majority of the places first investigated the pole of the magnet would always appear to the observer to describe its orbit in the same direction as the hands of a watch, so that on the whole when the needle was to the east of its mean position it would generally be falling, and when to the west rising. Unfortunately, however, this statement is not of universal application, as there are a certain number of stations on the west coast of America where the ordinary movement appears to be reversed. If figures representing a number of these magnetic orbits are arranged, in order from north to south, as in Fig. 3, and if those selected are appropriate to places the longitude of which is not very far distant from that of Greenwich, it is found that in passing from north to south the area enclosed by the figure becomes larger, and that it again diminishes when the equator is passed. In other words, for these stations the rule holds good that the orbital sweep of the needle is greatest near to the equator. There is ananother curious peculiarity, namely that for stations of approximately the same latitude in the northern and southern hemispheres, respectively, the curves are larger in the Southern Hemisphere.

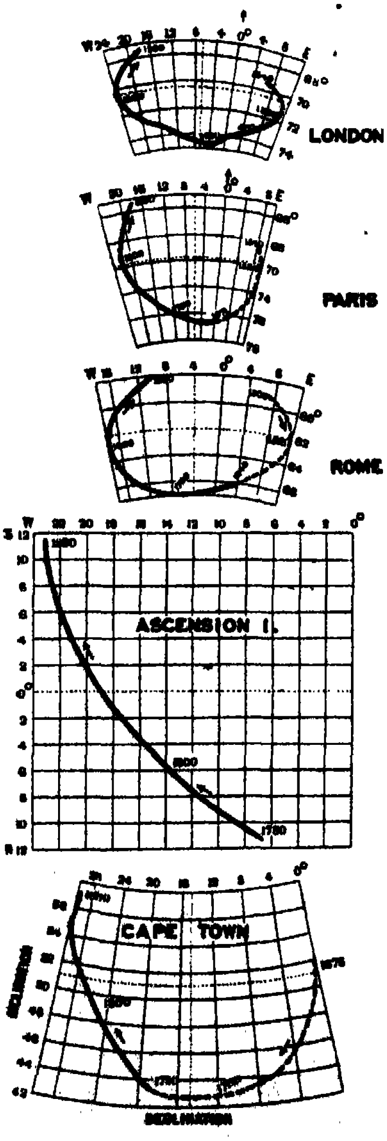

Fig. 3.

If, however, we turn to the American continent, the curves are different, the range of declination is less, and the figures, instead of being of an approximately circular form, become elliptical.

In no case have the phenomena been registered for a sufficiently long time to enable us to complete any one figure. For London we have fairly accurate data for about three centuries, and the earlier observations enable us to extend the curve still further backwards with some probability of accuracy. In the case of our own country we have probably followed the movement of the needle from an extreme easterly position attained in the time of Elizabeth to an extreme westerly position which was reached about 1824, but we have no right to assume that the return journey from west to east will occupy the same time as that which has been watched from east to west.

The first conclusion, then, which I wish to draw from these figures is that they and others like them display what is practically the whole of our knowledge as to the time during which magnetic phenomena go through a complete cycle of change. Calculations have been given by high authorities, which lead to the conclusion that the magnetic pole would perform an orbit round the pole of the globe in about 960 years; but a glance at the curves is sufficient to show how uncertain are the data upon which such estimates are based.

The speed with which the secular orbit is described does not appear to be constant. It may be more or less rapid in the future than in the past. The curves, though so far smooth and continuous, may in the future develop loops or irregularities of various kinds. We may doubt whether all the orbits are described in the same time. It is quite possible that the paths may not return into themselves, or be repeated in successive cycles.

These difficulties may be illustrated by another suggestive device of Dr. Bauer's. Let us suppose for a moment that the principal part of the magnetic system of the earth consists of forces due to currents or magnetic matter which are unchangeable and are arranged symmetrically with respect to the geographical axis. Let there be superimposed upon this another magnetic system describing within the earth and around the geographical axis an orderly orbit completed in an unknown term of years. Let us further suppose that this second system is itself unalterable except in position, so that, as it revolves, the magnitude of the forces is unchanged though the position of the points from which they emanate varies. Under these circumstances we should be able to foretell from the present state of the earth what the future cycle of change would be. If the magnetic needle were placed at some fixed point on the surface of the earth, it might take hundreds of years for the revolving magnetic system to make one complete revolution so as to take up every possible position with regard to the needle. But if the needle were suspended like Mahomet's coffin near to the surface of the earth, and were held there while the globe rotated beneath it, then in a single day the relative positions of the revolving magnetic system and the suspended needle would undergo every possible change, and the pole of the needle would describe in twenty-four hours the path which may in reality be accomplished in a millenium.

Of course we cannot thus suspend a magnet in space, but the same end would be attained by carrying it round the globe along a parallel of latitude, and we have sufficient knowledge of the magnetic conditions of the surface of the earth to determine the curve which the pole of the needle would describe during such a journey.

Three of these curves have been drawn by Dr. Bauer for the equator and for latitudes 40° N. and 40° S., and a glance at the diagram on which they are depicted shows that though they are larger, they bear a general resemblance to the secular curves which portray the movements of the needle at various stations near to the prime meridian. In particular the curious difference in the size of the orbits for equal latitudes north and south of the equator respectively is reproduced. Dr. Bauer has drawn curves for three different dates, of which only those corresponding to two are here reproduced (Fig 4), and of course, if the basis of our argument were unimpeachable, they should be identical. This is not so; there are noticeable, although not very great, differences, but, together with other facts already mentioned, the variations are sufficient to enable us to affirm that the secular change cannot be deduced in this simple fashion from the present magnetic state of the earth.

There is one other point with regard to the curves which shows how great must be our caution in arguing from such data. In the lower parts there is a general similarity with the curves deduced from past observations with the magnet at different places near the prime meridian, but in the upper portions, which refer to the future, the curves are more complicated, and they are varied by irregularities and loops of which we have, as yet, had no actual experience. Dr. Bauer has observed most praiseworthy caution in deducing any definite conclusions from these interesting speculations. But even if we refuse to accept his hypothesis that there is a more than accidental connection between the secular curve which the pole of the magnet describes at any one place, and the curve which it would describe if carried round the earth in the latitude of that place, there can be no question that it is possible that irregularities similar to those seen in the one set of curves may in the future occur in the others, and that any deduction which we may make as to the period of the magnetic cycle from the past, may be woefully falsified by future events.

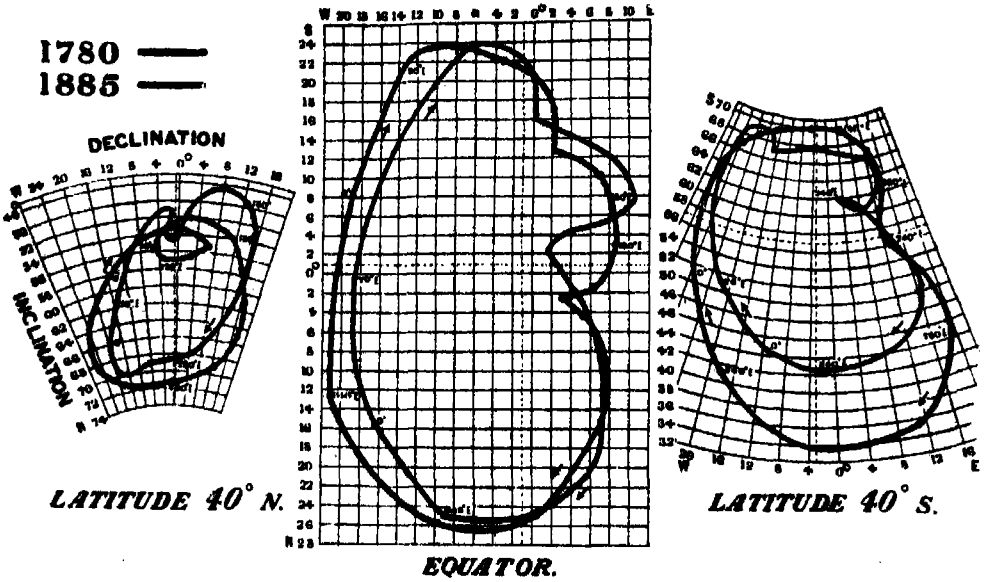

FIG. 4.

It is instructive to compare with this speculation the results obtained by Captain Creak from a comparison of the maps of the magnetic state of the earth drawn by General Sabine and those which Creak himself elaborated with the aid of the observations made by the '*Challenger* expedition. The conclusion to which he came was that during the forty years which elapsed between the epochs for which the maps were drawn, the secular change might be best represented by supposing that the magnetic poles were stationary, but that at certain points on the surface of the earth the forces of terrestrial magnetism had been increasing or diminishing. I have before now referred to these interesting observations in public, and I will not dwell on them again, except to remark it is possible that we may have to deal with causes both of the one type and of the other, that within the earth there may be a rotating magnetic system, and that purely local causes may also alter the intensity of the magnetic forces at different places.

Dr. Schuster has recently shown that a motion of the magnetic pole might be produced if the space round the earth were conducting. The conditions under which this would occur cannot be discussed now, but the magnetician has reason to be grateful for any hint as to a possible physical explanation of the secular change.

In addition to the long-protracted changes which have been discussed, the pole of a freely-suspended magnet also describes an orbit from day to day, which is so small, when compared with the secular path, that hitherto I have neglected it. This diurnal change has long been studied. Its magnitude varies from time to time and has been found to be connected with the season of the year and with the sunspot period. On these comparatively well-known facts I will not dwell, but there is one point in connection with the diurnal variation which has recently been attracting attention. For days together the orbits described may be very similar, but this regular motion is frequently disturbed by violent perturbations, and the pole of the magnet moves within a few minutes both to the west and to the east to an extent far exceeding that due to the ordinary diurnal motion, so that the form of the path is widely irregular. Such a phenomenon is called a magnetic storm, and from the fact that such storms occur simultaneously at places which are widely distant it has been thought that it is possible that they are due to some impulse which reaches the earth from the sun. They are also closely connected with displays of the Aurora Borealis. These irregularities make it difficult to determine what is the true normal behaviour of a freely suspended magnet. The most obvious plan for determining the average movement of the needle is to take the mean of its positions at each one of the twenty-four hours for every day in the year. The disturbances just referred to will thus be included in the calculations, but as very great magnetic storms are comparatively rare, the final value will not be very largely affected. This process is very laborious, and exceeds the powers of any except the best equipped observatories. Some time ago, therefore, it was suggested that the calculations should be shortened by the selection of quiet days only, on which it was to be supposed that the behaviour of the needle was normal. Five days in each month were considered sufficient, and by a happy arrangement all the English observatories have agreed that these days shall be chosen by the Astronomer Royal, and that thus the determination of the normal movement of the needle shall be made by all of them from data collected at the same time.

Attention has recently been drawn to the fact that, whatever the convenience of this five-day method may be, it leads to the conclusion that at the end of a quiet day, the needle does not return to the position which it occupied at the beginning. This point has been carefully investigated by Dr. Chree, and may be illustrated by means of the curve which I have drawn from the Kew Observatory Report for the summer of 1895, the scale of which is many times larger than that of the secular orbits already depicted (Fig. 5). The upward and downward movement of the needle is much smaller than the displacement east and west, so that an elongated figure is produced, but the interesting point is that it is not a closed curve; the two ends do not meet, but are separated by a very appreciable interval. It would, of course, be an easy explanation of this fact, if we could attribute it to the secular change. Just as the moon, though at the end of a month in the same position with respect to the earth as it was at the beginning, is much further advanced in the earth's orbit, so the diurnal magnetic variation must accommodate itself to the larger secular movement of which it is a subordinate part. But this explanation alone will not suffice. It is true that during the quiet days the movement of the needle in its secular path continues, but there is a good deal of evidence to show that it is of more than average speed. This is especially true of the horizontal force, which is gradually increasing and increases with remarkable rapidity on quiet days. Hence the secular movement appears to be checked by the storms. The comparatively rapid progress which has been made in quieter times, being retarded and even reversed during the periods of irregular motion which I have described.

It is true that General Sabine many years ago showed that magnetic storms do not act equally in both directions upon the needle, and that thus the phenomena which I am now describing can hardly be said to be recently discovered; but the method of presenting it which has been adopted by Dr. Chree, and which I have slightly modified by including in the diagram the variations both of declination and of dip, certainly places the facts before us in a novel and a striking light. Of what the cause of the sudden check which the needle receives during the magnetic storms may be, we can as yet say nothing. It is one of the puzzles which has yet to be unravelled.

The last point to which I will refer is one upon which more definite results have been obtained. Terrestrial magnetism is connected with phenomena which occur in the sun, with the Aurora Borealis in the upper atmosphere, and with the earth currents which traverse the soil. I have now to draw your attention to its relation to geology.

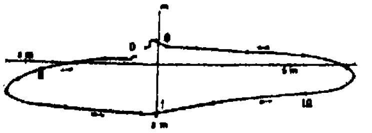

FIG. 5.

It has long been known that just as the great secular variation of the magnet is accompanied by minor diurnal changes, so the large alterations in the direction of the compass and dipping needle, which are observed when we move from place to place on the surface of the earth, are affected by irregularities which are apparently due to purely local causes. Thus the declination is greater in Ireland than in England; but the increase is not uniform as we pass from one country to the other. In fact in some districts an abnormally large increase is followed by a decrease.

These curious inequalities must be due to local disturbing forces, and the large number of observations which have been made in this country have enabled us to determine with more than usual accuracy the magnitude and direction which the magnetic forces would assume if they were undisturbed by any local cause, and from the difference between things as they then would be and things as they actually are, we can calculate the magnitude and direction of the disturbing forces themselves. When these are represented on a map, it is found that there are large districts of the country in which the disturbing horizontal forces act in the same direction; in one region the north pole of the needle will be deflected to the east, in another to the west, and, as we pass from one of these districts to the other, we always find that at the boundary the downward vertical force on the north pole of the needle reaches a maximum value. We are thus able to draw upon the map lines towards which the north pole of the needle is attracted. It is found that the exact position of these can be determined with considerable accuracy, and that the lines can be traced without any possible doubt through distances amounting, in some instances, to a couple of hundred miles. The key to this curious fact is probably furnished by observations in the neighbourhood of great masses of basalt or other magnetic rocks. If these were magnetised by the induction of the earth's magnetic field, the upper portions of them would in this hemisphere attract the north pole of the needle; and it is found that where large masses of basalt exist, as in Antrim, in the Scotch coal-fields, in North Wales, and elsewhere, the north pole of the needle is, as a matter of fact, attracted towards them from distances which may amount to fifty miles. The thickness of the sheets of basalt is in most cases too small to furnish a complete explanation of the observed facts, but it is quite possible that these surface layers of magnetic matter are merely indications of underground protuberances of similar rocks from which the surface sheets have been extruded. At all events, there is no possible doubt of the fact that where large masses of basalt occur, the north pole of the needle tends to move towards them.

There are other regions where the attractions are manifest, but where, nevertheless, no magnetic rocks occur upon the surface; but it is most probable that the cause is the same, and that it is due to the mere accident of denudation that in one case we can, and in the other we cannot, point to the magnetic rocks to which the anomalous behaviour of the compass is due. If this be so, it is certainly interesting that magnetic observations should enable us to penetrate to depths which the geologist cannot otherwise reach, and that the lines which we draw upon the surface of the map, as those to which the north pole is attracted, may, in fact, roughly represent the ridge-lines of concealed masses of magnetic rocks, which are the foundations upon which the deposits studied by the geologist have been laid.

There is some ground for thinking that if these great underground wrinkles exist, they have affected the rocks which are superposed upon them, especially those which are of a comparatively early date. As a general rule, if older rocks appear in the midst of newer ones, the pole of the magnet will be attracted towards the protruding mass; but this rule holds good only of the rocks of carboniferous or pre-carboniferous age, and does not apply to later deposits. As a striking example, I may remind you that the Pennine Range—which is sometimes called the "Backbone of England"—is a mass of millstone grit rising amid younger rocks. Down this a well-marked magnetic ridge-line runs. Similarly, in the neighbourhood of Birmingham, the Dudley and Nuneaton coal-fields are surrounded by more modern deposits. A curious horse-shoe shaped ridge line connects these two, and then runs south to Reading, which is, magnetically speaking, one of the most important towns in the kingdom. East and west from Dover to Milford Haven, and then across the Irish Channel to Wexford, runs a ridge of the older rocks called by geologists the Palæozoic Ridge, concealed in many places by newer deposits. Hollowed out in this are the South Wales and Forest of Dean coal-fields, and in another hollow within it lies the coal which has recently been discovered at Dover. Closely following this protruding mass of the older rocks is a magnetic ridge-line which passes through Reading, and we thus have a magnetic connection between the anticlinals of Warwickshire and the Palæozoic Ridge. From the neighbourhood of Reading also another magnetic ridge-line runs southwards, entering the channel near Chichester. M. Moureaux, who with most untiring energy has for many years been investigating single-handed the magnetic constitution of France, has discovered the continuation of this line on the French coast near Dieppe, and has traced it through the north of France to some fifty miles south of Paris. The energy which is now being displayed by magnetic surveyors in many countries will, no doubt before long, prove that the network of these magnetic ridge-lines is universal; and the relations between them and the geological conformation of the countries in which they lie will be so studied that our inductions will be based upon an adequate knowledge of facts.

This, at all events, we may hope, that amid the flux and change of magnetic forces with which we have so largely been occupied, we may have found in these ridge-lines physical features of the country as permanent as the hills themselves.

And now that I draw near to the end of my lecture, I cannot but feel that it has to a certain extent been wanting in organic unity. It is sometimes possible to unfold the story of a scientific advance in strictly dramatic form. The question posed, the oracle consulted, and the answer given, might well form the titles of the three acts in the modern miracle-play of scientific discovery. But the drama has its conventions, and even those authors who boast of their realism, too often falsify by over-emphasising the points on which they chiefly dwell. If we would know life we must learn it not from the stage-box or dress circle, but by mingling with mankind. If we would know what scientific work is, we must not be content with listening only to skilfully-told tales of scientific triumphs, but must penetrate into the observatory or laboratory, where the fear of failure, and the uncertainty of long watching and waiting, are at least as frequent visitors as the assured forecast of success.

To-day, therefore, I have dealt with problems which are still surrounded by doubt and difficulty, with questions which can only be answered by the combined work of many men, it may be of many generations. It is true that on some of these matters we are gradually acquiring definite knowledge. That earth-air currents, if they exist at all, are very minute in northwestern Europe; that the diurnal variation on quiet days is not necessarily to be regarded as normal; that local magnetic disturbances are due to forces so wide in their range that it is worth while to study them; these are all facts about which we were in doubt a few years ago, and on which we are in doubt no longer. But greater questions which lie behind these are still unanswered, and if I have ventured to deal with difficulties as well as with certainties, it has been because I have wished to give you a correct idea of current scientific thought on the subject of terrestrial magnetism.

MR. MERRIFIELD'S EXPERIMENTS ON THE RELATION OF TEMPERATURE TO VARIATION.

FOR the last ten or eleven years Mr. Frederic Merrifield, of Brighton, has been conducting a most elaborate and extensive series of experiments in the rearing of lepidopterous insects under various conditions of temperature. The results obtained by him are of high interest, both in themselves and also in reference to similar experiments independently undertaken by Dorfmeister, Weismann, Standfuss and others, some of which have already been noticed in the pages of NATURE. It is proposed to give here a short general account of the chief of Mr. Merrifield's experiments, with figures of some of the main results obtained. For full details the reader is referred to the original accounts which have appeared from time to time in the *Transactions* of the Entomological Society of London.

Experiments in 1887.—The first experiments undertaken had the object of supplying data for an inquiry by Mr. Francis Galton on the subject of heredity. It was anticipated by Mr. Galton that "the experiments would elicit incidentally many interesting results, some perhaps quite disconnected with the objects immediately in view." This anticipation was fully borne out by the facts.

The first species taken for experiment were two geometer moths, *Selenia bilunaria*, Esp. (*illunaria*, Hb.), and *S. tetralunaria*, Hufn. (*illustraria*, Hb.), both normally double-brooded in this country. Larvæ of both species were reared from eggs laid by females of the spring emergence; some of the moths resulting from these were selected for pairing according to size, three classes being formed, of maximum, medium and minimum expanse of wing, and the rearing of fresh generations was continued. Some of both species were fed up in the open air; these showed nothing remarkable. Others (of *S. bilunaria*) were kept during all their stages at a temperature of about 80° F., which had the effect of considerably accelerating their development. Five generations of *S. bilunaria* (counting the moths of the spring emergence as the first generation) were thus produced in the course of the year. These bred moths were all of the summer or *juliaria* form, and the females were always larger than the males, which is in accordance with the rule for the natural summer brood. The pairs selected for maximum and minimum expanse of wing produced no fertile eggs after the third generation. The fourth generation consisted entirely of the offspring of one of the medium-sized pairs of the third, and from these a selection was again made as before. The resulting moths of the fifth generation emerged in December and January, showing signs of deterioration. Only one of this brood laid fertile eggs, and these failed to hatch. The average size of the moths increased continuously up to the fourth, but diminished in the fifth generation.

Experiments in 1888.—The summer of 1888 was cold and wet, and the moths of both the selected species reared from larvæ kept in the open air showed signs of degeneration. That this was not due to the domestication of their progenitors appeared from the fact that a wild strain of *S. tetralunaria* behaved in the same manner.

It was observed in the case of *S. bilunaria* that the specimens produced from larvæ and pupæ that had been kept at about 80° F. showed a warmer colouring and fewer spots than those reared throughout their stages at ordinary temperatures. The same was found to be true in a still more marked degree of another species of geometer moth, *Ennomos autumnaria*, Wernb., and also, though to a less extent, of *S. tetralunaria*.

Experiments on the pupæ of *S. tetralunaria* led to interesting results. It was found that moths derived from pupæ of the summer brood, first retarded in development by freezing, though ultimately forced for a few days, tended, especially in the females, to assume the appearance of the comparatively dark spring emergence. Some larvæ of the same summer brood and their resulting pupæ were forced from the beginning, with the result that the same batch split into two divisions, the first of these feeding up rapidly and emerging, during the same season, with the summer colouring; the second taking much longer, and attempting to lie over for the winter as pupæ. A continuance of the forcing process brought out some of the latter in November and December, with the summer colouring. Others were exposed out of doors from November 7 to January 1, when they were brought into the house and again forced. The moths from this latter group came out in January and February, and were all of the spring colouring. Inasmuch as the continuously forced batch gave the summer form as late as December, it would appear that retardation alone is not in all cases sufficient to determine the assumption of the spring coloration. On the other hand, some pupæ of *S. tetralunaria* reared by Mr. Jenner, which were similarly trying to lie over for the winter, produced under forcing a series of intermediate forms becoming on the whole more and more like the spring type with the length of time that elapsed before their emergence. Here there was no exposure to winter cold; but only retardation from constitutional causes.

Mr. Merrifield remarks that the case of *S. tetralunaria* shows that the alternate succession of the two forms is not a necessary accompaniment of seasonal dimorphism. The same appears from Weismann's earlier experiments, in which, under appropriate conditions of temperature, the summer form *Vanessa prorsa*, L., was found to give rise in the next generation to *V. prorsa* instead of to *V. levana*, L. (the spring form).

The different reaction of members of the same brood of *S. tetralunaria* to the same conditions of temperature is interesting as an example of what may perhaps be called "physiological dimorphism"—a principle which there is reason to think is widely prevalent in nature, and which probably favours the survival of those species that exhibit it.

Experiments in 1889.—These had two main objects, the first being to determine the amount of exposure to cold that could be borne in the different stages, the second to ascertain more definitely the effect upon the perfect insect of temperature conditions applied during the immature periods.

Under the first head it was found that the eggs of both species of *Selenia* were injured by protracted icing; a temperature of 80° to 90° F., on the other hand, did no harm and quickened their development. Some eggs of *S. tetralunaria* gave another good example of physiological dimorphism. Thirty eggs were iced for seventeen days. On their removal from the ice-box, two hatched at once; none of the rest yielded larvæ until from eleven to thirteen days afterwards, when nineteen of them also hatched.

Icing the larvæ of *S. tetralunaria* was found to be rapidly fatal, and cooling injurious. The older larvæ stood cold better than the young ones. Larvæ of *S. bilunaria*, *S. tetralunaria*, *E. autumnaria* and *E. alniaria*, L., all endured a continuous temperature of 80° F. or a little more without apparent injury; but one of 90° to 100° F. was very detrimental.

Further experiments showed that no harm resulted from icing for moderate periods the pupating larvæ and pupæ of *S. tetralunaria* and the pupæ of *E. alniaria*, nor from cooling to about 47° F. the pupating larvæ or pupæ of *E. autumnaria*.

Under the second head some interesting conclusions were arrived at with *E. autumnaria*, *E. alniaria* and *S. tetralunaria*. Eggs from a single pair of the first-named species were divided into batches, and larvæ and pupæ of each batch were brought up under carefully regulated conditions of temperature. The same general result was obtained as in the 1888 experiments, but the additional fact was established that "it was in the pupal state that the effect was in the main produced. The forced pupæ, whatever the treatment of the larvæ had been, invariably produced pale and comparatively spotless moths; the cooled or iced pupæ, whatever the treatment of the larvæ had been, invariably produced dark and much spotted moths." It was found that a temperature of 63° F., or even higher, was low enough to produce the darker form. The treatment of the larvæ, though of slight effect compared with that of the pupæ, did not seem to be entirely without influence on the perfect insect; *e.g* the specimens that had been forced only as pupæ were darker than those that had been forced all through. Some individual variation was noticed in all the groups. Similar experiments on *E. alniaria* gave results tending in the same direction, but less regular and striking.

The effects on *S. tetralunaria* were far more marked than in 1888. Pupæ of the summer brood were iced for periods successively increased by two weeks up to twenty weeks. These yielded moths becoming generally, but not regularly, more and more like those of the spring emergence, both in colour and pattern, as the period of icing was lengthened. The converse experiment of forcing pupæ of the autumn brood, which would naturally give rise to the spring form of the perfect insect, proved very injurious to the pupæ, the majority of which died even when the temperature was kept at 60° F. only. The moths that emerged were irregular in their time of appearing, and poor in condition. In colouring they were intermediate between the summer and spring forms, those that remained longest in the pupal stage being as a rule the darkest. This autumn spring brood, like the corresponding brood in *V. levana*, is evidently far more resistent in its colouring to temperature conditions than the summer one.

In all three species it was found that the period of pupation was longer for males than for females: most so in *E. alniaria*, least in *S. tetralunaria*.

The broods of *S. tetralunaria* that had fallen off in 1888 showed still further deterioration, both as to health and size, in the spring emergence of 1889. But some eggs of the degenerate race that were sent to Wimbledon produced once more much larger, more numerous and more healthy moths. The cause of this was apparently the change of condition, and especially the substitution of cherry for birch as the food plant.

As a result of this year's experiments, Mr. Merrifield came to the conclusion that the predisposition to assume one or other form in a seasonally dimorphic species can in some cases be completely controlled by external influences applied to egg or larva before the end of its growth; but not, except partially, after larval growth is finished.

Experiments in 1890.—In the course of 1890 the new fact was established that different portions of the pupal period were of different importance for the changes induced by temperature, and that the pattern or outline of the markings could be made to vary independently of the general colouring. It was proved to be possible to obtain by difference of treatment, from the same brood of a seasonally dimorphic species, individuals showing (1) summer markings with summer colouring, (2) summer markings with an approach towards spring colouring, (3) spring markings with summer colouring and (4) spring markings with almost the spring colouring.

A brood of spring larvæ of the light-coloured strain of *S. tetralunaria*, which would naturally have produced moths of the summer form, was forced as a whole; pupating in June. Some of the pupæ were kept at 80° F., these produced well-marked summer forms (Fig. 1). The rest were iced for about twelve weeks, and then either forced or put out of doors. Those that were forced after icing produced moths all of which had the summer colouring, and most of which showed the spring markings (Fig. 3). Some of these which were cooled at 43° F. after the colours of the wings had begun to appear under the forcing process, showed no difference from the rest. Those that were put out of doors after icing (temperature at 8 a.m. averaging about 57° F.) gave moths with the spring markings and a dark colour in some cases almost reaching that of the spring emergence (Fig. 4). Similar experiments on two other broods gave corresponding results, and showed that, in some instances, from two to three days forcing during the last part of the pupal stage might be enough to produce a very marked effect upon the colouring. Another brood, of the third generation, which fed up rapidly and pupated before the middle of August, gave rise at the ordinary temperature of the room (between 65° and 70° F.) to moths of the usual summer markings and colouring, but slightly darker than their forced parents. When twelve of these had emerged, the remaining pupæ were cooled at about 43° F. Those moths that emerged after twenty-six days cooling, while still showing the summer markings, presented an approach to the spring coloration (Fig. 2).

Some striking results were also obtained with *E. autumnaria*. Forcing the pupæ produced, as in 1889, pale and comparatively spotless moths (Fig. 5). When the pupæ were cooled for fourteen days or more before forcing, the ground colour became dulled and the spotting blurred. Pupæ cooled for seven to twenty-eight days and then kept at the ordinary temperature of the room gave rise to moths as a rule very much darker than those finally forced; darker even than moths from pupæ that had been cooled for five or six weeks before forcing. The darkest moths of all were obtained from pupæ cooled for five or six weeks and then allowed to develop at the ordinary outdoor temperature, or this followed by cooling (Fig. 6). Even in these, forcing after eight days' exposure out of doors was found sufficient to counteract largely the tendency to darkening.

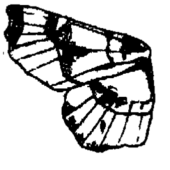

FIG. 1.—*Selenia tetralunaria*. Summer markings and colouring. (Forced.)

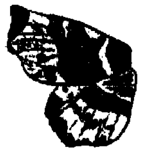

FIG. 2.—*Selenia tetralunaria*. Summer markings, spring colouring. (Cooled.)

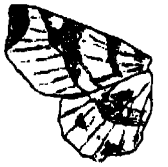

FIG. 3.—*Selenia tetralunaria*. Spring markings, summer colouring. (Iced, then forced.)

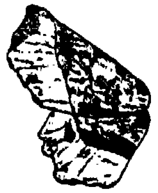

FIG. 4.—*Selenia tetralunaria*. Spring markings and colouring. (Iced.)

All the above were obtained from summer pupæ. Figs. 1, 3 and 4 are from the same parents. The difference should be noted in the shape of the inner area of the wings between Figs. 1 and 2 on the one hand, and Figs. 3 and 4 on the other.

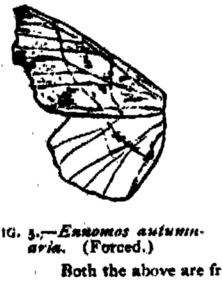

FIG. 5.—*Ennomos autumnaria*. (Forced.)

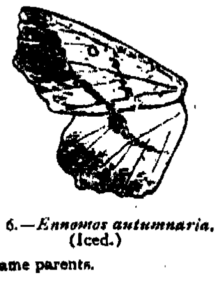

FIG. 6.—*Ennomos autumnaria*. (Iced.)

Both the above are from the same parents.

Experiments with *S. tetralunaria* and *E. autumnaria*, on the effect of moisture applied during the pupal stage in combination with various kinds of temperature, gave negative results.

A few trials of the effects of temperature on *Vanessa urticæ*, L. and *Lasiocampa quercus*, L., var. *callunæ*, were made this year, with the general result that cooling the pupa caused enlargement of the blue and dark marks in *V. urticæ*; while forcing the pupa caused increased paleness in *L. callunæ*, making it approach in aspect the ordinary *L. quercus*.

The suggestion was thrown out by Mr. Merrifield that the changes of pattern produced by temperature might assist investigators in tracing the evolution of the wing-markings in modern forms.

Experiments in 1891.—The first result established in 1891 was that the spring emergence of *S. tetralunaria* could be made by forcing during the penultimate pupal period to assume the colouring but not the markings of the summer form. In respect to the colouring it was found to be almost or quite as sensitive to temperature as the summer form, but in respect to markings it was completely resistent. The duration of the pupal period could in no case be shortened to that of the summer form; early and continued exposure of the winter pupa to a temperature of 80° F. or even of 60° F. generally proved fatal.

Experiments on the pupæ of both spring and summer broods of *S. lunaria*, Schiff., and *S. bilunaria*, and on the spring brood of *Falcaria falcataria*, L., gave the same general result of darkening in the cooled specimens and paling in the forced; and previous conclusions with regard to *S. tetralunaria* received confirmation.

In the case of *V. urticæ*, which was this year more completely investigated, it was found that a moderately low temperature generally deepened the colouring slightly, lowered the tone of the yellow patches, and spread the dark portions, especially the borders, enlarging also the marginal blue crescents.

Further experiments were also tried with *Lasiocampa quercus* and its variety *callunæ*. As in the former examples, exposure to a temperature of 80° F. was found to cause lightening, and to a temperature of 47° F. darkening, of the general ground colour. In *L. callunæ* the effect was most pronounced in the males. Some of the forced *callunæ* would, so far as regards colouring, be classed as *L. quercus*. *Arctia caja*, L., was found to be a species unusually intolerant of low temperatures, many pupæ dying when exposed to 50° or 60° F. In those that emerged there was a tendency for the dark spots on the hind-wings to spread and become confluent, and for the black transverse abdominal bars to increase in length and breadth. At 80° to 90° F. the brown of the fore-wings was paler than normal, and the red of the hind-wings took on a yellower shade.

The results obtained in this and former years seemed to Mr. Merrifield to afford evidence that besides the marking and coloration, the size and (less markedly) the shape of the wings might be affected by temperature. In most of the species tried the forced appeared to be smaller than the cooled specimens, and in the three species of *Selenia* a lengthening and increased angularity of the fore-wing seemed to result from a lowered temperature. In *V. urticæ* little difference was observed except in those from pupæ at 47° F., which were generally smaller than the others.

Temperature experiments on *Papilio machaon*, L., *P. podalirius*, L., (spring emergence), *Thais polyxena*, Schiff., *Argynnis paphia*, L., *Cerura vinula*, L., *Agrotis comes*, Hb., and *Attacus cynthia*, Drur. (all *winter* pupæ), gave negative results, as also did a careful trial of the possible effect of darkness and of different coloured light on *S. tetralunaria* and *A. cynthia*.

Experiments in 1892.—The experiments made this year were chiefly on butterflies; the first species taken being *Picris napi*, L. Pupæ of the summer brood were forced at 90° F. or kept at about 67° F. These yielded perfect insects of the ordinary summer form. Others of the same brood were iced for from three to four months; some were then exposed to an artificial "spring" temperature of 54° F., and the rest were forced at 80° F. Both of these two classes showed most of the characteristics of the usual spring form; *e.g.* on the upper surface greater suffusion and less intensity of dusky colouring; on the under surface faintness of the spots on the fore-wings and strongly marked nervures on all wings, with increased strength of the yellow parts. Those forced after freezing had the nervures more strongly marked than the rest, but in other respects partook less distinctly of the spring colouring. About one-fourth of the pupæ resisted attempts at forcing, and "went over" to the following spring, thus affording another instance of "physiological dimorphism."

A second species taken was *Vanessa atalanta*, L., which gave interesting results. About 100 pupæ were divided into six classes, and treated as under:—

(1) 80° to 90° F., emerging in 6 days.
(2) About 64° F., emerging in 18 or 19 days.
(3) About 56° F. (equable); emerging in about 34 days.
(4) 51° to 64° F. out of doors, averaging about 54°; emerging in 44 days.
(5) 45° to 58° F., averaging about 51°; emerging in about 40 to 50 days.
(6) 45° F. for from 32 to 47 days, then to various temperatures ranging from 90° F. (emerging in 6 days more) down to a mean of about 55° (emerging in from 19 to 34 days more).

Classes 2, 3 and 4 did not greatly differ among themselves or from the normal; their coloration, however, seemed on the whole to increase in intensity with the lowering of the temperature. In Class 1 the black ground-colour was slightly suffused with golden brown, the scarlet band was broadened, and its intensity of colour somewhat diminished. A new scarlet spot appeared on the under surface of the fore-wing (Fig. 9). In Class 5 the pale costal patch on the under surface of the hind-wing became more pronounced, and showed an increased tendency to spread along the costa. A light ochreous cloud about the middle of the hind margin of the same wing-surface, visible in normal specimens, became more strongly marked. In Class 6 the scarlet band was tinged with carmine, narrowed in area, and broken up by transverse bars of black. There was a tendency in the fore-wing to the diffusion of white and lavender scales over the black ground-colour, and round the edges of the white spots. The submarginal black spots of the hind-wing were often centred with lavender, occasionally a row of minute blue spots appeared in the margin of the dark portion of the hind-wing, and another on the extreme border of the wing itself (Fig. 10). On the under side there was more diffusion and blurring of markings, with an increased tendency towards the multiplication and spreading of pale areas.

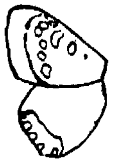

FIG. 7—*Chrysophanus phlæas.* (Diagrammatic.) Forced; showing large size of black spots on fore-wing, and diminished breadth of copper border on hind-wing.

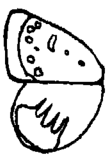

FIG. 8.—*Chrysophanus phlæas.* (Diagrammatic.) Iced; showing diminished size of black markings, and increased breadth of copper border. The latter has lost its external serrations, and shows prolongations passing inwards along the nervures.

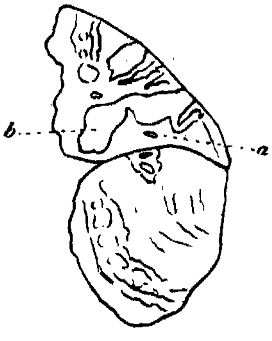

FIG. 9.—*Vanessa atalanta*, under side. (Diagrammatic.) Forced; shows appearance of new red spot (*a*) between scarlet band (*b*) and inner border of fore-wing.

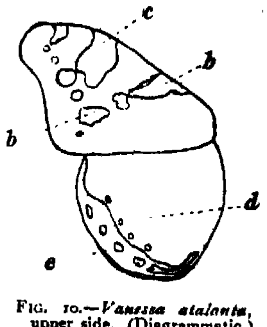

FIG. 10.—*Vanessa atalanta*, upper side. (Diagrammatic.) Cooled; shows scarlet band (*b*) broken up, enlargement of white costal mark (*c*), new row of minute blue spots (*d*). The submarginal spots of the hind-wing (*e*) are centred with lavender.

Chrysophanus phlæas, L., a species which had already been worked at by Weismann, was also made the subject of a series of temperature experiments. Well-marked differences were found to exist between the extreme forms produced under conditions of heat or of cold. The former caused enlarged size and diminished intensity of the black spots, a narrowing of the coppery band on the hind-wing, and a dusky suffusion of the fore-wings, especially towards the bases (Fig. 7). Under the latter, the black spots are much reduced in size, the coppery parts are lighter, and the coppery band on the hind-wing broadens, loses its posterior serrations, and often shows prolongations along the nervures towards the base (Fig. 8). These effects are noteworthy inasmuch as they differ considerably from the results of heating and cooling in other species. Their peculiar relation to the temperature conditions is also remarkable; thus, summer pupæ kept at 33° F. for ten weeks, if afterwards allowed to remain at 55° F., gave the cold form in its extreme development; but if forced at 90°, gave the heat form almost as perfectly as those kept at 80° to 90° all through. Another curious point is that whereas a temperature of 47° F. was very injurious to the pupæ, they bore icing at 33° F. for ten weeks without damage.

Leucophthalmia punctaria, L., which was also tried during this year, gave results in some respects like the above. Thus, though forcing at 90° F. or icing at 33° were borne without injury, exposure to 45° proved harmful. Again, as in *C. phlæas*, "a temperature of 33° F. seemed to suspend the physiological changes without much other effect," for the pupæ exposed to this temperature for over three months, and afterwards forced, gave the heat form in almost as complete a state of development as those forced from the beginning. Summer pupæ were used for the experiment, and the general effect of cooling was to cause "gradual disappearance of the submarginal blotches, increase of dark sprinkling, and intensification of the central line as the temperature was lowered."

To Mr. Merrifield's account of his experiments during this year a short paper was appended by the present writer, giving reasons for considering certain of the modifications produced in *V. atalanta* by both heat and cold to be ancestral in character.[1] Some of the new features produced by heat were considered to show an approach towards *V. callirrhoe*, Hb., and some of those produced by cold appeared to indicate reversion to a still older form of *Vanessa*.

Experiments in 1893.—A number of winter pupæ of *Pieris napi*, L., were divided into groups, some being forced in February and March, others left to emerge out of doors, which they did in late April and early May. The two divisions showed the same kind of difference, though in less degree, as was apparent in the summer brood of 1892 between those forced throughout and those cooled for the greater portion of their pupal period.

Experiments on both summer and winter pupæ of *Pararge egeria*, L., showed that the general effect of forcing was to lighten the ground colour and cause the pale spots to become smaller and less well defined. In no case was any approach shown to the bright ochreous colouring of the South European form.

In *Hydriomena silaceata*, Hb., cooling the summer pupæ caused an approach towards the usual colouring of the spring emergence; while forcing, besides producing a more uniform appearance, generally diminished the size of the perfect insect.

A trial was also made of the summer pupæ of *Araschnia levana*. The results were in general accordance with those previously obtained by Weismann; the effect of a raised temperature being to produce the dark *prorsa* form, and that of low temperatures (from 48° F. downwards) being to cause the appearance of the pure *levana* type, a few of those only exposed to moderately low temperatures showing slight traces of the intermediate *porima* colouring.

Interesting experiments were made on four species of *Vanessa* —*V. polychloros*, L., *V. atalanta*, L., *V. c-album*, L., and *V. io*, L. Pupæ of *V. antiopa*, L., gave negative results, probably in consequence of being already too far advanced when their treatment began.

In *V. polychloros*, high temperatures caused a general lightening of the ground colour and the appearance of yellowish clouds and streaks; the ordinary black spots were sharply defined. It was found that yellowish marks made their appearance to a greater or less extent when a temperature of 80° or upwards was employed, even if the pupæ had previously been cooled or iced for some weeks. When exposed to low temperatures, the pupæ produced perfect insects with a deeper and duller ground colour and a spreading of the dark marks, especially of the submarginal band. The enlargement of this band was always observed in cooled or iced specimens, whether subsequently forced or not. The whole ground-area was generally dusted with black scales, which tended to form new spots, especially in a row parallel to the outer margin in both fore- and hind-wing (Fig. 13).

Fresh experiments on *V. atalanta* confirmed the previous year's results and added new ones. Forcing temperatures up to 100° F. were employed, with the result of killing many of the pupæ. Those specimens that emerged showed a scarlet cloudy patch in that portion of the fore-wing which corresponds to the centre of the ocellus in *V. io*; and some of them showed another new scarlet spot on the under side of the fore-wing, in addition to the new spot observed in 1892. One of the apical white spots tended to be loosely ringed with scarlet in the forced, and with white in the cooled specimens. The latter were generally undersized.

In *V. c-album* it was found that both the first and second brood, but especially the first, became darker if exposed to a moderately low temperature.

Forced specimens of *V. io* showed a tendency to the development of dark spots near the apices of the nervular interspaces. Cooled and iced specimens showed a tendency, increasing as the temperature was lowered, for the dark costal "claw-mark" of the fore-wing to lose its regular curve and become angulated, for the apical pale spots to separate themselves more distinctly from the remains of the dark submarginal band, and for the bluish constituents of the ocellus in the hind-wing to divide themselves into two parallel series, a marginal and a submarginal. The resolution of the ocellus in the fore-wing was in one specimen very complete (*Fig. 11*).

A paper by the present writer drew attention to the further reversionary features disclosed by the temperature modifications above described, and commented on the significance of these phenomena with reference to the centripetal and centrifugal theories of heredity.

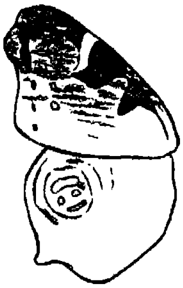

FIG. 11.—*Vanessa io.* (Diagrammatic.) Iced; showing resolution of ocellus.

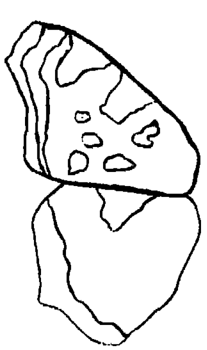

FIG. 12.—*Vanessa polychloros.* (Diagrammatic.) Forced; shows size of black marks somewhat reduced. The yellow markings are not represented.

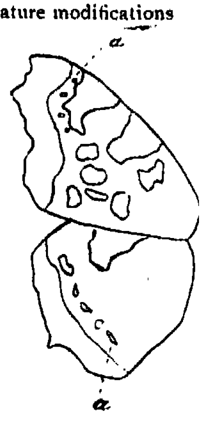

FIG. 13.—*Vanessa polychloros.* (Diagrammatic.) Iced shows tendency to formation of new submarginal row of black spots (*a*) in fore- and hind-wing.

Experiments in 1894.—Pupæ of *Limenitis sibylla*, L., were found to be intolerant of heat. Those that survived a temperature of 85° to 90° F. gave rise to perfect insects with a slight increase of reddish scales near the apex of the fore-wings and the anal angle of the hind-wings. The orange-brown of the under surface was enlarged in area and paler in colouring. Exposure to a temperature of 48° F. for from three to five weeks caused a sprinkling of the white band with black scales, and on the under surface an increase in area and intensity of some of the darker parts with a tendency to suffusion and spreading of the white.

As a result of further experiments on *Vanessa c-album*, it was found that in certain of those exposed to low temperatures, which were not well borne by this species, there was an increase in the distinctness of the submarginal series of dark spots. Some of these were pupilled with bluish or lavender scales, as in the Chinese *V. c-aureum*, L., which appears to present an early form of the *Vanessa* pattern.

A few experiments were also made on *V. cardui*, L., giving results in accordance with those previously obtained by Standfuss in Zürich.

Experiments in 1895.—Both high and low temperatures (98° F. and 33° F.) were found to be well borne by pupæ of *Gonepteryx rhamni*, L. Little change was produced in the appearance of the imago, but the general effect of the low temperature was to reduce or abolish the orange discoidal spot on the fore-wing of both sexes, while under the high temperature the pale hue of the female appeared to assume a yellower tinge. In one instance this effect was well marked.

---

[1] Weismann has expressed his general concurrence with these and subsequent conclusions of the present writer as to reversion (*Neue Versuche*, Jena, 1895, pp. 51, 72).

In *Vanessa atalanta* some further changes were observed as the result of high temperatures; the most remarkable of which were the appearance of a scarlet patch on the fore-wing between the red cross-band and the costa, and a long streak of grey-blue scales near the inner margin of the same wing. The most efficacious way of producing these modifications in this and other species of *Vanessa* appeared to be the use of a temperature of 95° F. to 102° F. for 12–14 hours at an early stage, afterwards gradually lowered, but still kept up to 85° F. or more till near emergence.

Some cooled specimens of *V. urticæ* bore great resemblance to the northern variety *polaris*. Heated specimens were like the southern form *ichnusa* in the shade and extent of the red ground colour, and also in the tendency towards disappearance of the isolated dark spots on the fore-wing. All three spots, however, were affected in these specimens, whereas in *ichnusa* the spot nearest the hind margin retains the normal appearance. Other changes were observed in the outer border, and in the shape of the fore-wing, the angulation being diminished.

Pupæ of *V. antiopa* at a low temperature gave similar results to those obtained with this species by Dr. Standfuss, but they were much less marked.

Experiments in 1896.—Pupæ of *P. daplidice*, L., from eggs laid in March, kept at a temperature of 70° F. to 80° F., gave the ordinary summer form. Some of the same batch, kept in the open air after five or six weeks' cooling at 52° F., emerged as the spring form *bellidice*. In *Melitæa didyma*, Esp., cooling at 51° F. was found to produce an extension of the black markings on the under side of the hind-wings. Of two specimens forced at 94° F., one was of an abnormally fiery tint.

Some specimens of *Saturnia pavonia*, L., from North Italy, forced in late winter and early spring, were much paler, ruddier and more uniformly coloured than those kept out of doors. This species is therefore not so resistent to temperature-conditions as many other winter pupæ.

Vanessa urticæ, var. *polaris*, from Lapland, was found to be sensitive to temperature, though less so than specimens from Central Europe.

Further experiments during the present year (1897) have shown that the tawny ground colour in *Argynnis paphia*, L., is brightened, and the size of the dark markings reduced by warmth, while the contrary effect follows exposure to cold. Also in *Aporia cratægi*, L., a low temperature causes much thickening and spreading of the black lines which mark the course of the nervures.

This ends the series of experiments so far undertaken and carried out by Mr. Merrifield. It is to be hoped that he will be able to continue and extend researches so interesting in themselves and so valuable to science. The present paper is concerned with facts only, not with their interpretation; but it must be obvious to any one who considers the remarkable results here briefly recorded, that they constitute an important contribution towards the better understanding of many disputed questions.

It may be well in conclusion to give Mr. Merrifield's own enumeration of the kinds of change observed. "The changes produced by temperature," he says, "are mainly of three kinds, viz. (1) general change, often striking, in the colouring, without material alteration in the pattern or form of the markings, but often with much enhancement or diminution in their intensity; (2) change caused by the substitution of scales of a different colour, either singly and generally distributed so as to be scattered, or so grouped as to cause a material change in pattern; (3) change in general appearance caused by imperfection in the development of scales or of their pigment. No. 1 seems a direct effect of temperature, not affecting vigorous development. Under No. 2 are to be ranged the most radical changes in pattern, as in the extreme case of *Araschnia levana-prorsa*, which have been explained on the theory of reversion to an earlier form. In No. 3 the wings are often somewhat reduced in size; the scales are scanty, irregularly placed, and often misshapen and deficient in pigment, the membrane of the wing showing between them. The three are more or less combined in many cases."

The figures which illustrate this paper were drawn from the plates which accompany Mr. Merrifield's papers in the Entomological Society of London's *Transactions*. F. A. DIXEY.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Vice-Chancellor announces that he has opened a University Benefaction Fund, to which he has placed during the present term donations for various academic purposes amounting to nearly 3500*l.* This sum includes a gift of 1000*l.* from Dr. Peckover, Lord-Lieutenant of Cambridgeshire, and a grant of 1050*l.* from the Mercers' Company for the rebuilding of the medical schools. The family of the late Sir George M. Humphry, Professor of Surgery, have contributed 600*l.* towards the latter object, by way of a memorial gift; and Mr. H. Westwood Hoffman, 100*l.*

The Rede Lecturer for the ensuing year is Sir Henry Irving. Prof. Ewing, F.R.S., has been appointed Chairman of Examiners for the Mechanical Sciences Tripos. Mr. A. F. Stabb has been appointed University Lecturer in Midwifery.

The examinations in Sanitary Science will begin respectively on April 19 and April 26, 1898, the incidence of Easter having rendered the advertised dates inconvenient.

A scheme of theoretical and practical training has been organised for members of the University who are intending to become masters in public schools. The scheme is under the direction of the Teachers' Training Syndicate, and will be carried out in connection with the existing Day Training College. Certificates of efficiency will be granted to candidates who have pursued the prescribed course and passed the examinations of the Syndicate.

THE Council of the Institution of Civil Engineers have awarded a Salomons scholarship of 50*l.* to Mr. Edward Ernest Tasker, a student of the Technical College, Finsbury.

THE University of Upsala has received from Mr. Franz Kempe the sum of 150,000 knonor (about 8333*l.*) for an associate professorship of plant biology. Dr. Lundström has been nominated to occupy the chair.

SINCE the beginning of the academical half-year (states the *Lancet*) all students attending the chemical and physical laboratories of the University of Heidelberg have been insured against accidents happening in the course of the lectures, of the laboratory work, and of scientific excursions. The insurance premium is paid by the treasury of the University, which has also made a new regulation in connection with the subject requiring the students to pay a small sum in addition to the class fees.

A Fellowship to be called the Geoffrey Fellowship, of the value of 100*l.* a year for three years, has been presented to Newnham College, Cambridge, and will be awarded in June 1898. The Geoffrey Fellow will be required to reside at Newnham College, and to pursue independent study in some department of learning, letters or science. Candidates must be women who have obtained honours in a Cambridge Tripos Examination or in the Oxford Final Schools. They should send in their names to Mrs. Verrall, President of the Associates of Newnham College, before May 1, 1898. Each application should be accompanied by a statement of qualifications, a scheme of the work which the candidate proposes to carry out, and, if possible, a dissertation or other evidence of work done. Further information respecting conditions of tenure, &c., may be obtained from Mrs. Verrall, Newnham College, Cambridge.

SPEAKING at Northampton a few days ago, Lord Spencer urged that great efforts should be made to improve secondary education in England. Much had been done for education in the Victorian age, but it was absolutely necessary to fill the gaps existing between primary education and University education. He trusted that the measure which the Government would introduce would be satisfactory to all educationists, and he knew if it was it would have the support of even the opponents of the Government. One of the great difficulties in the way of carrying out technical education was the want of good secondary education. No more useful measure had been passed during the reign of the Queen than that giving county councils and borough councils grants for technical education, for it had stimulated a desire for secondary education and technical education. What was now wanted was a measure which would put technical education on something of the same basis, though not perhaps under the same supervision, as primary education. More aid was wanted from public funds and from rates. When they had that they would have attained something of great benefit to the people of the country. Technical education was necessary. He was not one of those who could see for a moment that the prosperity of England was on the wane. But if England meant to keep her position in the commercial world she must not be behind with regard to the most important thing which had arisen in modern days connected with commerce—namely, the necessity of giving technical instruction to those who had to work in England's commercial market.

SCIENTIFIC SERIALS.

American Journal of Science, December.—A microsclerometer, for determining the hardness of minerals, by T. A. Jaggar. This instrument depends upon the energy required to make a boring of a certain diameter and depth under a given weight and by means of a diamond point of a cleavage tetrahedron of perfect shape. The hardness is measured by the number of turns required to make the boring, or by the depth reached after a certain number of revolutions. The depth is measured by a microscope attached to the boring point, by bringing successive divisions of a slanting micrometer scale into focus. The values found for the hardness of Mohs's scale-minerals show even greater gaps than those obtained by Pfaff and Rosival. Taking corundum as 1000, topaz is 152, quartz 40, orthoclase 25, apatite 1·23, fluorite 0·75, calcite 0·26, and gypsum 0·04.—On the sapphires from Montana, by G. F. Kunz. Sapphires were first found in transported gravels along the bars of the Upper Missouri, then in the earthy products of decomposed dikes, and lastly further down in the unaltered igneous rock itself. Much beautiful material has already been obtained, but little of high value.—On the corundum-bearing rock from Yogo Gulch, Montana, by L. V. Pirsson. The dikes of igneous rock containing sapphire and corundum are of a dark grey, basic appearance, and have an uneven fracture. In thin sections it appears as a dark lamprophyre, consisting mainly of biotite and pyroxene. There is a little iron ore present, but much less than is usually seen in rocks of this class.—Electrical measurements by alternating currents, by Henry A. Rowland. Gives some twenty-four methods of measuring inductances, capacities and resistances by means of alternating currents. Some of these depend upon a new principle in the shape of an adjustment of two currents to a phase difference of 90°. This is done by passing one current through the fixed, and the other through the suspended coil of an electrodynamometer. The fixed coil may then be made to carry a heavy current, and the sensitiveness of the apparatus is greatly increased. Inductances can be compared to within 1 in 10,000, but care must be taken not to twist the leads, as their electrostatic action is then very great. The question of standard inductances is thus practically solved.

The latest issue of the *Isvestia* of the Russian Geographical Society is of exceptional interest. It contains, first, a brief sketch, by P. K. Kozloff, of the Roborovsky's Tibet expedition, in which the author dwells especially upon his own "excursions"—that is, the journeys which he made separately from the main body of the expedition, and gives very valuable data relative to the nature, and especially the animal world, of the visited regions. The reports about the journey in the Sy-chuan province, and to the Southern Kuku-nor ridge are especially interesting.—The geologist, E. E. Anert, contributes a very valuable sketch of his journeys in Manchuria. He started from the Suifun river, near Vladivostok, and went first to Ninguta, and then to Ghirin, the capital of Manchuria, where he took a boat and went down the Sungari till its junction with the Amur. The great Manchurian river, up to Ghirin, has been described already in 1864, by the expedition of Colonel Chernyaeff, who had with him the astronomer Usoltseff and P. Kropotkin; but the papers of these two explorers, which were printed in the *Memoirs* of the Siberian Geographical Society, were destroyed, as well as the original maps, during the Irkutsk conflagration, and remained almost quite unknown to geographers.—A third paper, of great interest, is by V. I. Lipsky, who was the leader of the Hissar expedition of 1896. Notwithstanding great difficulties, due to heavy snowfalls in winter, which were followed by heavy rains in spring, Lipsky explored the Hissar ridge from the south. The heights of the passes are from 12,000 to 14,000 feet. Ten new glaciers were discovered; they all lie above the 10,000 feet level, and are all surrounded by large moraines testifying to their previous larger extension.—The fourth paper is by Th. K. Drizhenko, who was at the head of a hydrographic expedition for the exploration of Lake Baikal in 1896. The paper is accompanied by a map of the lake showing the positions of the 100, 400 and 700 fathoms depth-lines, and another map showing the distribution of surface temperature during the month of August. The work of the expedition was continued this summer as well.—In the same issue G. V. Levitsky discusses the advisability of having a few seismic observatories in Siberia and Central Asia, each provided with a horizontal pendulum.

SOCIETIES AND ACADEMIES.

London.

Royal Society, December 9.—"On the Refractivities of Air, Oxygen, Nitrogen, Argon, Hydrogen, and Helium." By Prof. William Ramsay, LL.D., F.R.S., and Morris W. Travers, B.Sc

In the course of an investigation on the nature of helium, many measurements of the refractivities of different samples were made with a view to determining their composition.

Since, on account of the great difference between the refractivities of air and helium, it was found inconvenient to compare the two gases directly, the helium was compared with hydrogen, and the refractivity of the hydrogen was afterwards determined with regard to air. As a check the hydrogen was subsequently compared with oxygen, and nitrogen free from argon, these gases were also measured against one another, and against air. At a later stage in the investigation the refractivities of argon and carbon dioxide were also determined.

The measurements were made by the interference method described by Lord Rayleigh (*Proc. Roy. Soc.*, 59, 198-208).

Special attention was paid to the purity of the gases examined, and a full description of the methods of preparation is given in the paper. It is possible that the discrepancies between the results obtained by various observers may be due to the presence of impurities in the gases which they employed.

The mean values obtained for the refractivities of the gases examined are tabulated below.

Refractivities of Gases, Air equal to Unity.

	Directly compared.	Through Oxygen.	Through Nitrogen.	Through Hydrogen.	Through Argon.
Hydrogen	0·4733	0·4737	0·4727	—	—
Oxygen	0·9243	—	0·9247	0·9237	0·9261
Nitrogen	1·0163	1·0155	—	1·0170	1·0192
Argon	0·9596	0·9577	0·9572	—	—
Carbon dioxide	—	1·5316	—	—	—

Calculated from the determinations given above, assuming Dale and Gladstone's formula for mixtures of gases, the refractivity of air becomes 99·647 instead of 100.

Turning to the determinations of other investigators, it was found that since Dulong, in 1826, no single experimenter had made measurements of both oxygen and atmospheric nitrogen. Mascart determined the refractivity of nitrogen, and found it to be 1·0178, a value which closely agrees with the figure given above.

Lorenz determined the value for oxygen, 0·9347, but there is reason to doubt the purity of the gas which he employed. The refractivity of air calculated from the data of Mascart and Lorenz becomes 100·15.

Since the value obtained for the refractivity of air, calculated from the values obtained for oxygen, nitrogen and argon, differs from 100 by an amount far exceeding the limit of experimental error, we were driven to the conclusion that the refractivity of air is somewhat less than the refractivities of its constituents, taken in the proportion in which they occur.

It appeared advisable to try other mixtures; and a mixture of hydrogen and helium was first selected, because these are both very "perfect" gases, inasmuch as their critical points lie very low. It was to be expected that if a difference between calculated and found values should exist, it should be of the inverse character to that of a mixture of oxygen and nitrogen, for they are two somewhat "imperfect" gases. The result has borne out this idea.

A mixture was made of 20·60 c.c. of hydrogen and of 20·12 c.c. of helium free from argon, and of the density 1·960; and with the refractivity of the mixture those of hydrogen and helium were compared. Taking the refractivity of the mixture as unity, the following ratios were found :—

Hydrogen/mixture ...	1·5977 1·5957	Mean ... 1·5967
Helium/mixture ...	0·4513 0·4478	,, ... 0·4495

The calculated values are—

$$\frac{(\cdot 04495 \times 20\cdot 12)}{40\cdot 72} = 22\cdot 21$$

$$\frac{(1\cdot 5967 \times 20\cdot 60)}{40\cdot 72} = \frac{80\cdot 87}{102\cdot 99}.$$

Here the calculated value of the refractivity of the mixture is 3 per cent. higher than the found value, while with air the calculated value is 0·35 per cent. too low.

A third experiment was made, in which the "artificial air" was a mixture of 19·13 c.c. of carbon dioxide with 19·29 c.c. of oxygen, both gases supposed to be at 0° and 760 mm. Again, taking the refractivity of the mixture as unity we found the following ratios :—

Carbon dioxide/mixture	1·2450
Oxygen/mixture	0·7525

The calculated values are :—

$$\frac{(1\cdot 2450 \times 19\cdot 13)}{38\cdot 42} = 61\cdot 99.$$

$$\frac{(0\cdot 7525 \times 19\cdot 29)}{38\cdot 42} = \frac{37\cdot 78}{99\cdot 77}$$

Here, as with air, the total refractivity found is less than that calculated. It is true the difference is not great, but we are persuaded that it is real, for it considerably exceeds the error of our several determinations.

The case is not bettered if Lorentz and Lorenz's formula be substituted for Gladstone and Dale's. Using their formula, $n^2 - 1/n^2 + 2$, the calculated result is 99·72 per cent. of that found for air.

The coefficient of compressibility of hydrogen is too small, while that of other gases, such as oxygen and nitrogen, is too great. The effect of mixing equal volumes of hydrogen and helium, each of which has too large a coefficient of elasticity, is to cause each to occupy twice the volume that they previously occupied, and to halve approximately the pressure for each. The pressure is, therefore, lower than it would be for an absolutely ideal gas, for each gas, hydrogen and helium. The sum of these pressures will accordingly be too low, or transposing, the sum of the volumes will be too great. The opposite argument holds for air.

Now, in considering volumes, we deal not merely with the co-volume, *i.e.* the space occupied by the molecules, but also with the interstitial space inhabited by the molecules. But the refractive power, if Clausius's deduction from the formula of Lorenz and Lorentz is correct, is a function of the dielectric constant, and hence of the co-volumes of the gases. And here the discrepancy is more easily detected than by any determination of density. It must, therefore, be concluded that gases are not, as postulated by Dalton, indifferent to one another's presence, but that they modify one another's properties in the same manner as do liquids, though to a different extent. This mutual action at high pressures and small volumes modifies even the volume relations, as recently shown by Dr. Kuenen. And it must persist at low pressures and large volumes, though it may not always be possible to make measurements of pressure and volume accurate enough to lead to its detection. The refractivity, however, seems to be a means delicate enough to be used for this purpose."

"The Electric Conductivity of Nitric Acid." By V. H. Veley, F.R.S., and J. J. Manley, Daubeny Curator of the Magdalen College Laboratory, Oxford.

In this paper an account is given of determinations of the electric conductivity of nitric acid of percentage strengths from 1·3 to 99·97, purified from nitrous acid, sulphuric acid and the halogen acids. Special forms of apparatus, and special methods of measurements were adopted to overcome the difficulties of polarisation of the concentrated acid.

The chemical and certain physical properties of the practically anhydrous acid were studied; this acid has no action on various metals such as copper, silver, cadmium, mercury, magnesium, iron and tin, nor on calcium carbonate either at ordinary temperatures or at the boiling point. Sulphur and iron pyrites dissolve quickly and completely in the gently-warmed acid. The values are given for the corrected density at 4/4, 14·2/4 and 24·2/4 of the 99·97 acid, as also for thirty-two samples of acid of $K_0 \times 10^8$, $K_{15} \times 10^8$, $K_{30} \times 10^8$, viz. conductivity in mercury units, and for $\alpha 10^4$, and $\beta 10^6$, the temperature coefficients in the equation $R_t = R_0 (1 - \alpha t + \beta t^2)$. It is shown that whereas nitric acid behaves as other electrolytes in possessing a positive temperature coefficient of conductivity for percentage strengths from 1·3 to 96·12, yet from this point upwards it behaves as a metallic conductor. The results of the experiments point to the existence of hydrates of nitric acid containing $10H_2O$, $3H_2O$, $2H_2O$ and H_2O, with one molecular proportion of HNO_3 and of $1H_2O$ with $2HNO_3$, or $H_4N_2O_7$, the analogue of pyrophosphoric acid. Evidence is thus added to that previously accumulated of definite combinations of nitric acid with water.

Chemical Society, December 2.—Prof. Dewar, President, in the chair.—The following papers were read :—The representation of the isomeric benzene hexachlorides by Collie's space-formula, by F. E. Matthews. The author shows that Collie's space-formula for benzene satisfactorily explains the existence of two benzene hexachlorides; amongst other facts explained are the different stability of the isomerides and the formation of only two.—Compounds of piperidine with phenols, by O. Rosenheim and P. Schidrowitz. A number of addition products of piperidine and phenols or their derivatives of a salt-like nature have been prepared in which the phenol acts as an acid; they are crystalline, and are decomposed by strong alkalis or acids.

Royal Meteorological Society, December 15.—Mr. E. Mawley, President, in the chair.—Mr. W. Marriott read a paper on the rainfall of Seathwaite, Cumberland. This place has long been noted for its heavy rainfall, being in fact one of the wettest spots in the British Isles—the average yearly amount is 137 inches. The spring months of April, May and June are the driest, so they not only have the least rainfall, but also the least number of rainy days. August, the month when the Lake District is thronged with visitors, has the greatest number of rainy days. The heavy nature of the rainfall may be gathered from the fact that 21 per cent. of the falls are above 1 inch, 2 per cent. being above 3 inches. The greatest fall in one day was 8·03 inches on November 12. The author has investigated the atmospheric conditions under which the heavy rainfalls occurred at Seathwaite, and he finds that these heavy falls are due to the direction and force of the wind. When the wind is blowing strongly from the south-east or south-west, it will be concentrated in the valleys on the windward of Scafell, and rush up them with considerable force, the air current consequently being projected to a considerable altitude beyond Scafell. Owing to the reduction of temperature with elevation, the air parts with a great deal of its moisture, which falls as rain. With such a process going on continuously for a whole day, the heavy rainfall at Seathwaite is fully accounted for.—Mr. R. C. Mossman also read a paper on the daily values of non-instrumental meteorological phenomena in London from 1763 to 1896. The phenomena discussed were thunderstorms, lightning without thunder, fog, snow, hail and gales.

CAMBRIDGE.

Philosophical Society, December 6.—Mr. F. Darwin, President, in the chair.—Features of interest in the fauna of the Sandwich Islands (with exhibitions), by Mr. R. C. L. Perkins. Mr. Perkins exhibited and read some notes on some of the more interesting insects from the Hawaiian Islands. Several species of endemic dragon-flies (*Agrionina*) were shown, some of which passed their earlier stages in water, in the usual manner, while others in the nymph state lived amongst the leaves of a liliaceous plant, the diversity in habit having probably been brought about by the extreme poverty of the freshwater fauna, the terrestrial species being much more favourably situated in regard to a constant supply of food. A series of examples of three or four allied species of Longicorn beetles of the genus *Plagithmysus* were remarkable for their extreme variability in colour, in spite of their limited range. The varieties of each species fell into two or three groups, which were hardly, if at all, connected by intermediate forms. The differences between the extreme forms of a species were in some cases more striking than the differences between the species themselves. The habits of these beetles, and the several distinct sets of stridulating organs with which they are furnished, were also referred to. A collection of wasps from the islands of Molokai and Kauai were exhibited, to show the great difference in superficial appearance between those inhabiting the latter island, and those from the rest of the group. No protective significance could be attributed to the uniform and conspicuous markings of the Kauai species.—Remarks on a journey to investigate the habits and development of *Lepidosiren paradoxa*, by Mr. J. Graham Kerr. The author gave a short account of an expedition which he had made to the interior of the Gran Chaco of Paraguay for the purpose of investigating the habits and development of *Lepidosiren paradoxa*. He was aided by a grant from the Balfour Fund, and was accompanied by Mr. J. S. Budgett of Trinity College. Lepidosiren occurs in considerable quantity in the swamps towards the centre of the Gran Chaco boreal. It is sluggish in habits, wriggling slowly about among the thick vegetation of the swamp. At short but very irregular intervals it visits the surface and takes a breath of air. Its food consists mainly of large Ampullarias and masses of confervoid algæ. The young are to a greater extent vegetable feeders than are the adults. Lepidosiren makes a burrow in the ground at the bottom of the swamp, and lines it with soft grass. In this the eggs are laid. The papillæ on the hind limb of the male grow out into long filaments during the breeding season, and during life these are blood-red in colour. They appear to be ornamental structures. The eggs are very large—about 7 mm. in diameter. Cœlomic eggs have a thick gelatinous coat: in fertilised and developing eggs this becomes thin and horny. Segmentation is during its later stages holoblastic and unequal. Gastrulation takes place in a manner which recalls that of *Urodele amphibia*, and of Cyclostomes. Eventually a tadpole larva is hatched out. This develops large external gills and a very large sucker of the Amphibian type. The external gills and sucker disappear about six weeks after hatching. At the same time the colour of the young Lepidosiren becomes much darker, and they become much more lively in their habits. For the first ten to twelve weeks of its free existence the young Lepidosiren does not eat, but lives on the yolk in the walls of its gut. A remarkable habit of Lepidosiren was mentioned, in that their normally very dark colour becomes during the night nearly white. The black chromatophores shrink up during the hours of darkness, large yellow chromatophores which are also present remaining expanded. During the dry season the Lepidosiren retreats into the mud, in which it remains breathing by means of an air-hole until the waters return and set it free.

Edinburgh.

Royal Society, December 6.—The following are the president and vice-presidents for the coming session:—Lord Kelvin; Lord McLaren, Rev. Prof. Flint, Prof. McKendrick, Prof. Chrystal, Sir Arthur Mitchell, and Sir William Turner. Papers were read as follows:—On the food, fuel, and air of the world, by Lord Kelvin.—Chapters on the mineralogy of Scotland, chapter viii., Silicates, by the late Prof. Heddle.—Note on the disturbance of the magnetic and meteorological instruments at the Colaba Observatory during the earthquake of June 12, 1897, by N. A. Moos.—On a problem of Sylvester's in elimination, by Prof. E. J. Nanson.—On the velocity of graded actions, by Prof. Walker.—Preliminary note on a characteristic of certain chemical reactions, by Prof. Gibson.—On the directions which are most altered by a homogeneous strain, by Prof. Tait.

Mathematical Society, December 10.—Mr. J. B. Clark, President, in the chair.—The following papers were read:—Some questions in arithmetic, by Prof. Steggall.—Methods of solution of the equations of elasticity, by Mr. John Dougall.—Trigonometrical notes, by Prof. John Jack.—Note on a transformation of the equations of hydrodynamics, by Mr. Carslaw.

Paris.

Academy of Sciences, December 13.—M. A. Chatin in the chair.—The election of M. Ditte, as a Member in the Section of Chemistry, was confirmed by the President of the Republic.—On the work carried out in 1897 at the observatory at Mt. Blanc, by M. J. Janssen. The chief work done was on the value of the solar constant, although the observations were much interfered with by the unfavourable weather.—On the periods of double integrals, by M. H. Poincaré.—Signification of the number and symmetry of the fibro-vascular bundles of the petiole in the measurement of the perfection of plants, by M. Ad. Chatin.—On the first modifications of nerves in simple wounds of the cornea, by M. L. Ranvier. The nerve fibres of the cornea, which are divided by section, grow with an unexpected rapidity and activity, if they are in continuity with their origin cells.—Remarks, by M. Lœwy, on presentation of the annual publications of the Bureau des Longitudes.—On a new method for determining the vertical, by MM. J. Perchot and W. Ebert. The method of Deichmüller, floating a mirror in a bath of mercury, can be modified to give good results which are free from the prejudicial effects of capillary phenomena The results are as accurate as with the plain mercury bath, and good measurements can be obtained in Paris, where the amount of vibration renders the use of the plain bath very troublesome.—On the problem of Ribaucour, by M. C. Guichard.—On an analytical form of the integrals of linear partial differential equations of two independent variables, by M. J. Le Roux.—On the resolution of certain differential systems, by M. Riquier.—On a double generalisation of the equations of Lie, by M. E. Vessiot.—On the positions of unstable equilibrium, by M. P. Painlevé.—On the displacement of a plane of which all the points describe spherical lines, by M. Raoul Bricard.—The problem of the distribution of electricity and the problem of C. Neumann, by M. W. Stekloff.—New method of attacking platinum. Preparation of the bromoplatinates of ammonium and potassium, by M. Georges Méker. Platinum is attacked by a fused mixture of ammonium sulphate and bromide, although it resists the action of either salt taken separately. Ammonium bromoplatinate is readily isolated in a pure state from the fused mass.—On phosphorous oxide, by M. A. Besson. By warming together H_3PO_3 with an excess of PCl_3 on the water bath, and washing the product with water, a reddish solid is left, which on analysis gives exact figures for the oxide P_2O.—Properties of sodium carbide, by M. Camille Matignon. The carbide forms a white powder, not explosive by shock or by friction. On slight heating, it burns in air to sodium carbonate. In chemical activity, sodium acetylide far exceeds the corresponding calcium compound, nearly all the reactions being so violent that carbon is set free, and the sodium acting as in the free state.—On a new series of cyclic ketones, by M. A. Béhal. The fractional distillation of the heavy oil from wood tar, followed by conversion the benzoyl-oximes, has furnished two new ketones.—On the neutralisation of glycerophosphoric acid by alkalis, in presence of helianthine and phenolphthalein, by MM. H. Imbert and A. Astruc. The quantities of soda solution required to neutralise a given weight of glycerophosphoric acid in presence of helianthine and phenolphthalein respectively are as 1 : 2. A method for the estimation of the acid is worked out from these data.—Heat of neutralisation of glycerophosphoric acid, by MM. H. Imbert and G. Belugou.—New results relating to rachitis, by M. Œchsner de Coninck.—On species in botany, by M. Paul Parmentier—On polymorphism of branches in inflorescences, by M. H. Ricome. Branches of many inflorescences show differences among themselves. In branches in which the direction is near the vertical, the symmetry is normal. In branches much inclined to the vertical, this symmetry is more or less disturbed.—On the geology of the islands of Metelin, Lesbos, and Lemnos in the Ægean Sea, by M. L. De Launay.—On an apparatus generating leucocytes observed in the peritoneum, by M. J. J. Andeer. The peritoneum is the starting-point for the ostiolic apparatus of the whole animal. It is here shown that the peritoneum is also the starting-point for the genesis and formation of the elements of the blood.—Cholesterin and the biliary salts as a chemical vaccine against snake poison, by M. C. Phisalix. The bile salts exert the same protecting influence against snake poison as the bile itself.—On the entozoa of man in Normandy, by M. Ed. Spalikowski.

Amsterdam.

Royal Academy of Sciences, October 30.—Prof. van de Sande Bakhuyzen in the chair.—Prof. J. C. Kapteyn on the velocity with which the solar system moves in space. This velocity is deduced from the velocity in the line of sight of fifty-one stars measured by Vogel. It was demonstrated that from these velocities the sun's motion can be deduced with a weight more than seven times as great as that of the determination made by Vogel himself, if the ratio of the average velocity of the stars to that of the sun, previously communicated to the Academy, be made use of. Prof. Kapteyn found for the velocity of the system 10·4 ± 0·7 miles per second. From this, in connection with a previous communication, is further deduced the mean parallax of stars of different magnitude.—Prof. Hubrecht presented for publication in the *Proceedings* a paper by Dr. G. C. J. Vosmaer, of Utrecht, entitled "On the retrograde development of the blood-vessels in the omentum of the rabbit," and showed by means of camera sketches of the omen of rabbits (new-born, one day, four days, eight days) that Ranvier's "cellules or réseaux vasoformatifs" are the last remnants of a process of retrograde development of vascular tissues in this membrane.—Prof. Bakhuis Roozeboom on an inquiry made by Dr. Mohr into the behaviour of solutions of $NH_4Cl + FeCl_3$, on crystallising out. Besides the well-known double salt $FeCl_3.2NH_4Cl.H_2O(D_1)$, there were detected: $FeCl_3.NH_4Cl(D_2)$ and $2FeCl_3.NH_4Cl.4H_2O(D_3)$. They were obtained by a new method of evaporation at a constant temperature in a desiccator under the microscope. Some solutions, which precipitate D_1 on evaporation, dissolve it again, when the evaporation is prolonged. The mixed crystals, which can also be precipitated from certain solutions, probably contain Fe as D_1.—On behalf of Dr. Cohen the speaker made a communication to the effect that the irregularities observed in the Weston-element (Clarke's, with the substitution of cadmium for zinc) had been found to be caused by a transformation which solid cadmium sulphate undergoes at 13°. It suffices to heat the element a little above this temperature to restore its normal behaviour.—Prof. van Bemmelen presented, on behalf of Dr. Klobbie, a paper on equilibrium in the water-ether, water-malonic acid and ether-malonic acid systems, and the isotherm of the water-ether-malonic acid system at 15°.—Prof. van der Waals communicated, on behalf of Dr. P. Zeeman, a third paper on doublets and triplets produced by external magnetic forces. Dr. Zeeman, working with a Rowland grating, has succeeded in photographing the outer components of the magnetic triplet, the light of the central component being quenched by means of a Nicol. The negatives obtained in this manner, and specimens of which were shown at the meeting, are particularly adapted for measurements concerning the magnetic change. Measurements of one of the blue cadmium lines have given for e/m the value $2, 4 \cdot 10^7$. The experiments are being continued.—His inquiries into the action of nitric acid upon methyl amides have occasioned Prof. Franchimont to study also the action of nitric acid upon methyl nitramines, and he has found that even below 0° nitrous oxide and methyl nitrate are formed nearly quantitatively, which is more easily deduced from the formula $CH_3.NH.NO_2$ than from  $\underset{O}{CH_3.N—NOH}$. Methyl nitramine does not produce blue, violet, or green colorations with ferric chloride, though under certain circumstances a reddish-brown ferric salt may be obtained from it. Prof. Franchimont further presented, on behalf of Mr. P. van Romburgh, a paper on the occurrence of certain volatile products in tropical plants. Mr. van Romburgh has already examined more than 900 genera and found methyl alcohol in many of them, acetone in some of them, but methyl salicylate in many more of them, viz. in 18 per cent. of the number examined. Sometimes it occurs together with prussic acid. The volatile reducing substance described by Reinke and Curtius was also often detected and obtained as a liquid from indigo, rameh, and the leaves of sugar-cane.—Prof. Lorentz on the question of the relative motion of the earth and the ether. Remarks on a recent memoir by Prof. A. A. Michelson (*Amer. Journ. of Science*, ser. 4, vol. iii. p. 475). The author discusses the assumptions that are necessary in the theory of aberration.—Prof. Stokvis presented the dissertations of Mr. J. Keyzer, entitled "Ueber Haematoporphyrin im Harn," and of Mr. J. de Hartogh, jun., entitled "Ueber Peptonurie und den Nachweis des Peptons im Harn," and added some oral elucidations.

NEW SOUTH WALES.

Royal Society, October 6.—The President, Henry Deane, in the chair.—Note on mutilations practised by Australian aborigines, by T. L. Bancroft. The paper dealt with the object of the "Mika" or "Kulpi" operation of the Australian aborigines.—On a cordierite-bearing rock from Broken Hill, by J. Collett Moulden. This is believed to be the first time that cordierite has been recorded in Australia. It has a somewhat extensive development in the metamorphic rocks of Broken Hill, and is described in detail from two parallel exposures of granulitic rock about half a mile S.E. by E. from Block 14 Mine. The cordierite occurs in large crystals and also in grains through the granulite.—Note on the occurrence of a nickeliferous opal near Tamworth, N S. Wales, by D. A. Porter. Several years ago a specimen of opal brought to the writer was said to have been obtained in the "Never-never" ranges on the head waters of Attunga Creek, and not far distant from Mount Gulligal, Parish of Attunga, County of Inglis. Some little while ago, being in the vicinity, Mr. Porter found the locality and secured a few small specimens, one of which he forwarded to be exhibited before this Society. The mineral occurs in the form of small veins in serpentine rock, and is accompanied by veins of a pinkish or salmon coloured chalcedony, exhibiting a porcelain-like texture and broken surfaces.—Icebergs in the Southern Ocean, No. 2, by H. C. Russell, C.M.G., F.R.S. This paper was prepared as a continuation of one read before the Royal Society, September 4, 1895. It deals with the reports of icebergs seen since the end of July 1895. One hundred and two ships have reported ice in the interval; nearly the whole of the ice, so reported, was within the area enclosed between 40° and 80° east longitude and 40° to 62° south latitude; very few reports of ice outside that area have been received. It was shown that the *Thermopylæ* steamed for 1000 miles amongst icebergs, and that the ocean was clear one hundred to one hundred and twenty miles north of this track. Some idea of the number of icebergs may be gathered from the fact that the officers of one ship counted 977 bergs, and those of another ship 4500. This and the previous paper cover a period of six years, and it was shown that at times the icebergs come into, or leave the track of vessels in a few days; three instances in which there had been sudden disappearances were shown to be coincident in point of time with the advent in Australia and the ocean between the Cape and Australia of strong north to north-west winds.

MOTIVE POWER AND GEARING.

Motive Power and Gearing for Electrical Machinery. By E. Tremlett Carter, C.E., M.I.E.E., &c. Pp. xxii + 620. (London: *The Electrician* Printing and Publishing Company, Ltd.)

MR. CARTER has written a very interesting and very useful book on a subject of much importance for electrical engineers. The needs of electrical practice have had a great effect in stimulating the invention of quick-running steam engines, the improvement of gas engines, and the discovery of modes of transmitting power from the driving machine to the driven which did not formerly exist. An electrical engineer is all the better electrical engineer for being also a good mechanical engineer; but as he must master (if he is to be anything but the veriest rule-of-thumb mechanic) in the course of his training in the class-room and the workshop, a very considerable body of more purely electrical knowledge and practice, and, over and above, acquire some knowledge and experience in mechanical matters, the latter is the point in which, when starting on his practical career, he is apt to be most deficient.

Of course, for making all these things realities to a man, there is no education for the engineer like that of the workshop, provided his theoretical training in the principles of the scientific work he is to do (for scientific it ought always to be, or he is no true engineer), is carried on at the same time, just as for the scientific study of physical science there is no training like that of the laboratory carried on parallel with systematic discussion of physical theory and experiment in the lecture-room.

The electrical engineer, as we have observed, however, if properly trained, has always an inquiring spirit, and an observing eye, and an adaptability of self to circumstances, which enable him as he goes on in his work, and comes into contact with the considerable diversity of machinery which it is his lot to encounter, to gradually become a mechanical engineer of great resource and skill so far, at any rate, as his own department of work is concerned.

A book like Mr. Carter's, studied in connection with workshop practice by a capable man, or kept on the shelf in the dynamo room to be read and consulted when time or the requirements of work present opportunity, cannot but be of great service. The topics dealt with are many and various, and an enumeration of them would more than occupy all the space at our disposal, though it would bring out very clearly how great is the range of mechanical question and device with which the electrical engineer is now concerned.

The first chapter deals with fundamental principles, such as motive power, work, energy and its sources, inertia, waste power and useful power, load and load diagrams, dynamometry (more properly ergometry), and storage of energy. The order of treatment differs somewhat from that which in a complete discussion of such subjects would be regarded as logical, but it is, so far as it goes, quite scientific, though the ideas referred to are occasionally so general as to require a good deal of special discussion and elucidation, which of course must be obtained elsewhere.

In the discussion of reciprocating (or simple harmonic) motion, it would have been well to insert besides the statement that the numerical ratio of the acceleration to the displacement is a constant, that the value of this ratio is $4\pi^2/T^2$ where T is the period of the motion. This is a simple rule which is of real service in dealing with vibrations. The phrase "elastic forces of inertia" seems a little strange to the pure physicist; but of course what the author is insisting on, is the give and take action of a body, which in consequence of its inertia stores up energy in an accession of speed, and restores it again when the speed is diminished.

A beginning is made in this chapter of the important subject of the measurement of power. One or two forms of brake and of transmission dynamometer are described, and the general principles discussed, the further treatment being left till the systematic application of tests comes under review.

In this chapter also, it ought to be mentioned, the author treats of economy of design. Lord Kelvin's law of economy, though acted on to some extent, is not yet, it is to be feared, fully appreciated and acted on. It says really that improvement cannot be economically carried beyond the point at which the proper annual charge for the capital invested in an improvement of plant, is just equal to the annual saving effected by making it. Here is a point, of course, at which increase in the cost of materials and labour retards, and diminution in the same facilitates, improvement in design.

After a statement of the problem to be solved, which he puts in the form, "What are the best provisions which may be made for utilising the available energy for the performance of useful work and the production of a paying revenue?" the author proceeds to deal with the steam engine. This forms Part ii. of the work, and is treated under the headings: Fuels, thermodynamics, principles, steam, furnaces and boilers, theory and action of the steam engine, steam engine details, some typical steam engines, steam engine driving, the steam engine in relation to electric power, the management of steam plant.

After this enumeration of chapters, it will not appear surprising that this part comprises more than half the book by some twenty-two pages. All the chapters seem to us full of practical information, and of great value to electrical engineers. The sketch of thermodynamics given is perhaps that which is most directly open to criticism, not so much on account of what is included as of what is left out. There are, however, one or two points on which we would offer one or two slight remarks. First it would be well always, if the phrase "perfect gas" is to be used, to offer some direct definition of its meaning. Mr. Carter does so in his p. 73. Practically what he defines as a perfect gas is one which, under all conditions, fulfils the characteristic equation $PV/T =$ constant. But in the definition of T there seems a little looseness. Thus it is stated (same page), "taking the zero on the Fahrenheit scale as the standard it was found by Charles, that all gases expand 1/460 of their volume at this temperature when raised from any temperature to a temperature 1° F. higher." Then from this increase of volume for each degree of the F. scale it is inferred that the absolute zero is 460° F. below the ordinary zero. Logically this process is deficient in that it presupposes a known Fahrenheit scale; and there were just as many perfectly exact Fahrenheit scales as there were previously existing exactly made Fahrenheit thermometers. Our impression is that the law of Charles or Gay-Lussac expressed the fact that the different gases experimented on, all expanded by nearly the same fraction of their volume at the temperature of melting ice on being raised under constant pressure from that temperature to the "boiling point" of water. Then *this* expansion (from v_0 to v_{100} say) obtained accurately for any one gas enables $t°$ C. to be *defined* for *that* gas as thermometric substance as that temperature for which the volume of the gas under constant pressure is $v_0 + t(v_{100} - v_0)/100$, and so also for the Fahrenheit scale. Taking air, we get by this definition the air thermometer scale, which, having its own independent definition, can be used as a standard of comparison for other thermometric scales.

From this we get the absolute zero on this gas thermometer scale as that for which $t = -100\,v_0/(v_{100} - v_0)$ that is for which the volume of the gas is zero. Fulfilment of Boyle's law, if it exists, gives agreement of the similarly, but independently, defined constant volume scale for the same gas with the constant pressure scale. Thus we get an independent scale for each gas for which accurate experimental data are available, and the *numerical reckoning* of the absolute zero of temperature will not be necessarily the same for all. We say this with Mr. Carter's note on p. 107 in view. We believe that a perfect gas is best defined as one which obeys Boyle's law at all pressures and temperatures, and gives a constant pressure scale agreeing with the only properly absolute scale of temperature, that of Lord Kelvin, or, which comes to the same thing, as a gas which, besides fulfilling Boyle's law, has an invariable ratio of specific heats.

The second law of thermodynamics is hardly that given on p. 106, which is really the so-called "axiom" on which Lord Kelvin based the second law. The law itself is most shortly expressed by the equation $\int dq/t = 0$, where t is absolute temperature, dq a quantity of heat taken in (or given out) at temperature t, and the integral is taken round a reversible cycle. If t_0 be the lowest available temperature, the positive value which $-t_0\int dq/t$ has for every non-reversible cycle is Lord Kelvin's expression for the heat dissipated in the cycle.

We are rather disappointed that no treatment, *e.g.* the beautiful graphical treatment given by Maxwell, is included of the thermodynamics of change of state. By means of the Protean fundamental parallelogram of the Carnot cycle, the whole of the essential part of thermodynamics can be given in two or three pages. A statement from this point of view of the information which thermodynamic theory gives as to the density of saturated steam would not have been inappropriate here.

The account of furnaces and boilers and of steam engines generally seems very full and complete, but a full review of it is a thing to be undertaken only by an expert in these matters. No one, however, who takes an interest in engineering methods and results, and nothing can be more valuable for the physicist than their study, can fail to be struck with the fulness of the information given by Mr. Carter.

In Part iii. gas and oil engines are discussed, and we have, after a chapter on gaseous and liquid fuel, the Otto cycle, and engines working on this cycle are fully described. This, to us, is perhaps the most interesting part of the book. Prime-movers of this description have advanced immensely during the last ten or twelve years, and the lot of those who have to use them is cast in much pleasanter places. We have a lively recollection of having to toil with five or six enthusiastic laboratory students turning the fly-wheel for nearly half an hour at a time trying to get a large gas engine started. This and other difficulties, and the continual setting to rights which the engine required, would have tried the patience of a saint, and certainly were too much for ordinary mortals.

In Part iv. water motors and turbines generally are discussed, in Part v. gearing is dealt with, and in Part vi. we have a most valuable account of types of power stations.

The book, it ought to be mentioned, is one of several excellent practical works that have appeared by instalments in the *Electrician*. It is very thoroughly illustrated with excellent drawings: engines of all kinds, central power stations, details of machinery, such as valve gear, governors, injectors, &c. Some of these might perhaps have been worked up better, but most are good, and all are thoroughly business-like and intelligible. We regret that we have not space to deal with the work more adequately; but as it is, in fact, a collection of some three or four separate treatises of great value, any attempt to fully review it here is impossible.

We have nothing but congratulation for the author on his work. Electrical engineers are deeply in his debt.

A. GRAY.

A PIONEER OF MEDICINE.

Masters of Medicine. John Hunter, Man of Science and Surgeon. By Stephen Paget, with an introduction by Sir James Paget. 8vo. Pp. 272, with a frontispiece. (London: T. Fisher Unwin, 1897.)

MR. FISHER UNWIN has undertaken to publish a series of volumes dealing with the life and works of the great scientific men who have brought medicine and the allied sciences to their present state of perfection. The object of the series, which is under the general editorship of Mr. Ernest Hart, editor of the *British Medical Journal*, is to set before unprofessional readers a plain account of the lives and fortunes of the "Masters of Medicine," with such a survey of their work as may be necessary to show wherein they excelled.

John Hunter lends himself particularly to this method of treatment. Living only a hundred years ago, the founder of a great school of thought, the hero of a hundred orations by the most eminent surgical minds of the century, there exists plenty of material from which to construct a most readable biography. His life, indeed, has often been written but not always judiciously, for it is only of late years that the critical spirit, which has reduced the writing of history to a science, has begun to pervade the historians of medicine. Mr. Paget has performed his work excellently, for he has consulted original authorities and has availed himself, by the kindness of Miss Hunter-Baillie, of such documents belonging to the Hunter family as are now in her possession. Fresh light is thus thrown upon some of the more obscure points in Hunter's career, whilst the charming personality of Mrs. Hunter, who selected the words for Haydn's Creation, is brought into bolder relief.

John Hunter, the founder of pathology, or the science which deals with the causes and progress of disease, was one of the younger members of a very remarkable band of pioneers in medicine who were born within a few miles of each other in a remote country district of Scotland, and who flourished in the middle of the last century. First in seniority was Smellie, of Lanark, the great man-midwife; then Cullen, sometime professor of medicine in Edinburgh, born at Hamilton; after him came William Hunter, in some respects greater even than John, his youngest brother; and finally Matthew Baillie, nephew of the Hunters, and the most worthy disciple of his uncles. Smollett, too, was the intimate friend of Smellie, and so must have known the Hunters. It would be of extreme interest to know the factors which led to the production of such extraordinary talent in so circumscribed an area and for so limited a period. In the Hunter family no less than three sons of the ten children were extraordinarily gifted, and in each case their genius was directed towards medical science. That the genius was innate is clearly shown by the fact that John Hunter instantly became an accomplished anatomist, and that although he was an original thinker of the highest power, he was in many respects illiterate, and always had the greatest difficulty in expressing his thoughts in words. Beginning with nothing, John Hunter, after many years of struggle, achieved a foremost place amongst the surgeons of London. But it was by his teaching, rather than by his clinical powers, that he gained his reputation. Edward Jenner, in England, the discoverer of vaccination, and Dr. Physick, who lived to become the veteran exponent of his master's teaching in America, were amongst his house pupils, whilst all the foremost surgeons of the next generation had attended his lectures—lectures which cost his hearers but tenpence a-piece, as Mr. Paget points out, for they were near a hundred in number, the honorarium for the course being four guineas. Yet the lectures were of the most magnificent kind, for they comprehended the whole circle of the sciences round surgery. They were made at a great cost to Hunter, for his brother-in-law, (Sir) Everard Home says of them:

> "Giving lectures was always particularly unpleasant to him; so that the desire of submitting his opinions to the world, and learning their general estimation, was scarcely sufficient to overcome his natural dislike to speaking in public. He never gave the first lecture of his course without taking thirty drops of laudanum to take off the effects of his uneasiness. He was so diffident of himself that he trusted nothing to memory, and made me draw up a short abstract of each lecture, which he read on the following evening as a recapitulation to connect the subject in the minds of the students."

It is no wonder, therefore, that the toils of his practice, the cares attending the amassing of the nucleus of the magnificent museum now housed in Lincoln's Inn Fields, and the labours of teaching, early overweighted a body by no means strong. He suffered from angina pectoris for many years before his death, and was wont to say that his life was at the mercy of any rascal who chose to irritate him, and he was very irritable. He died suddenly at St. George's Hospital, October 16, 1793, on the same day, and perhaps at the same hour, that the unfortunate Marie Antoinette, Queen of France, was beheaded in Paris. He was buried in the vault of St. Martin's-in-the-Fields, whence the pious care of Frank Buckland rescued his remains in 1859, and they were re-interred in Westminster Abbey.

Mr. Paget has performed his task most excellently, and if the present volume is to be taken as a standard for the series the sale should be large. Not only is the book well and pleasantly written, abounding in anecdote, but it is most tastefully produced, so that the paper, the print, the binding, and the reproduction of a part of Sir Joshua Reynolds' portrait of Hunter are in every way admirable.

SELECTIONS FROM A DIARY.

The Journals of Walter White, Assistant Secretary of the Royal Society. With a preface by his brother, William White. Pp. vii + 285. (London: Chapman and Hall, Ltd., 1898.)

MOST of the Fellows of the Royal Society of more than twelve years' standing will retain a lively recollection of Mr. Walter White, whilom Assistant Secretary to the Society, and will look with interest into the present volume. Mr. White entered the service of the Royal Society in 1844, and in 1861 (not, as incorrectly stated in the preface, in 1853, "less than ten years") was appointed Assistant Secretary, which office he held until 1885. During this long period he had unusual opportunities of watching the inner working of the Society, and thus the development of scientific ideas and activities; and the reader of the diary of so shrewd and observant man as he was, would naturally expect to learn much. We are compelled to say at once that such expectations will not be fulfilled.

The first chapter, which contains entries in the diary up to the time of his attaining a post at the Royal Society, is interesting as showing how a man, brought up as a cabinet-maker, after pursuing diligently his trade for some years, by continued intellectual toil, bravely teaching himself, won his way, amid many discouraging circumstances, to a means of livelihood more congenial to his nature. It will probably surprise many of the Fellows of the Royal Society to learn that one whose great knowledge of languages and literature had often been of help to them, had spent so many of his earlier years at the joiner's bench.

The third chapter puts together a number of entries illustrating Mr. Walter White's intimacy with the late Lord Tennyson. From one of these entries we gather that it was a suggestion from Mr. Walter White which led the poet eventually to build a house at Haslemere.

The second and fourth chapters contain, together with other matters, entries relating to the Royal Society and science, the former chapter dealing with the period from 1844 to 1861, when Mr. White became Assistant Secretary; the latter with that from 1861 to 1884, the year before he ceased to hold office. The forty years which these two chapters cover were years in which science made remarkable strides, and years also during which important events took place within the Society. Mr. Walter White was literary rather than scientific in his leanings; still the records of the impressions made by the successive exposition of new scientific ideas upon one who listened to them in turn, near at hand, during so long a series of meetings of the Society could not fail to be interesting. We are told in the preface that the present volume is not the whole diary, but only selections from it. It is to be regretted that what has been published contains so little dealing with the weighty matters of science brought before the Society during the forty years, or with the effects produced by new ideas on those who were the first to listen to them. It is still more to be regretted that the selection has been so largely confined to matters which cannot justly be called by any other name than tittle-tattle and scandal. From his position Mr. Walter White was to a large extent a confidential servant of the Society. The Fellows were in the habit of talking to him freely, and often expressed themselves concerning scientific things and scientific persons in a familiar and unguarded manner. There could be no harm in Mr. Walter White writing down for his own delectation sayings which pleased him on account of their picturesque force, such as Mr. A.'s account of Dr. B.'s opinion about Prof. C.'s works and ways; but it is to be exceedingly regretted that Mr. William White should have thought it desirable to give publicity to gossiping statements, redeemed neither by wit nor by accuracy, the appearance of which can do little more than give pain to the living, or to the friends of the dead whom they concern. We hasten to add, lest the above remarks should excite curiosity, that the gossip in question will yield very little amusement where it does not give offence. We may add that the volume does not do justice to Mr. Walter White himself any more than it does to the leading men of science and the Royal Society; their conversation with him did not consist chiefly in finding fault with each other, nor was his chief delight in listening to them, and taking notes of their angry or idle words.

OUR BOOK SHELF.

Agricultural Chemistry. By R. H. Adie, M.A., B.Sc., and T. B. Wood, M.A. 2 vols. Pp. ix + 280, and vii + 229. (London: Kegan Paul and Co., Ltd., 1897.)

IN the preface this is described as an elementary text-book of chemistry, designed for students beginning the study of agricultural science, and adopting as its method the teaching of the subject by experiment. The book demands some attention, as it is written by the teachers of agriculture in the University of Cambridge.

We are often told that the only right way of teaching chemistry is by leading the student to be himself the discoverer of chemical facts and laws by a series of experiments, observations, and inferences. This method is certainly excellent as an introduction to the science, but it becomes too cumbersome as the scholar proceeds, and the teacher soon finds himself making important statements of which no demonstration is forthcoming. Nor are all parts of the science best learnt by the exhibition of experiments. It is, indeed, easier to learn grammar as grammar, than to discover grammar for ourselves by the analysis of a language.

The first of these small volumes is intended as an introduction to general chemistry; the second deals with the subjects of soil and manures, with a briefer reference to the constituents of plants, and the analysis of foods.

It is difficult to tell in what manner the book is intended to be used. The details of the experiments are often so imperfectly described, that it would be impossible for a student to perform them without further directions. The preface states that the book is especially intended as an aid to teachers; but if the teacher is to follow the course marked out, he must clearly have a great deal of other information to fall back upon. One cannot, however, resist the conclusion that a great many of the experiments mentioned are not meant to be performed, but merely to be talked about.

We need hardly say that a good deal of correct teaching is given, but the errors and deficiencies are not a few. R. W.

Notions générales sur l'Écorce terrestre. Par M. le Prof. A. De Lapparent. 8vo. Pp. 156. (Paris: Masson et C^{ie}., 1897.)

GEOLOGY can be made attractive enough by a good writer who divests the subject of those details which concern only the specialist. To learn the aims of the science and its main results are all that the general reader and the elementary student require; and it is well when, as in the present little work, a distinguished master is not only willing but able to produce such a sketch agreeably written as well as instructive. The subject is introduced in the course of six lessons, and the author, in the first place, deals with the early history of the globe, with seas and continents, and the external features of the earth in general. He passes on to consider various questions of physical geography, and the erosion of the land by rain, rivers, and sea. His remarks on the cutting away of river-courses so as in time to produce a *profil d'équilibre* are illustrated with reference to the Seine, which has excavated its channel almost to the lowest possible level throughout its main course. The method of accumulation of various sediments, and volcanic phenomena are next discussed. Upheavals and depressions and the sequence of rocks form the subjects of another lesson. Some account of the Paris Basin is given, and in conclusion there is a brief description of the principal geological formations. The work is illustrated by thirty-three figures of fossils, sections, and photographic reproductions. Among the fossils only the principal forms of life are indicated, such as a Sea-urchin from the Chalk, a Devonian Spirifer, Jurassic Ammonites, and a Fossil Bird. The student's mind is therefore not burdened with many names, but a perusal of the work will give him a clear general grasp of the principles and elements of geology. H. B. W.

The Dawn of Civilization: Egypt and Chaldæa. (Third edition.) By G. Maspero. Pp. xiv + 800. (London: S.P.C.K., 1897.)

THE third edition of "The Dawn of Civilization," the English translation of Prof. Maspero's "Les Origines," has just been issued. The three coloured photographic plates which were inserted in the second edition are here retained, while but few changes have been made in the text of the second edition of the work. The most considerable addition appears to be in the chapter dealing with the first Theban empire. Here the author gives a brief sketch of the conclusions that may be drawn from a study of the remains recently found by Prof. Petrie between Ballas and Naqâda. Towards the end of the sixth dynasty the Libyans, yielding to a migratory impulse, overran the western frontier and established themselves in Egypt, leaving a permanent record of their presence in the burying places and remains of villages which extend the whole length of the mountain chain from Siût to Gebelên. Prof. Maspero does not go so far as Prof. Petrie, who would regard the whole of the south of Egypt as having been wrested from the native kings by this "new race"; he does, however, conclude that these Libyan settlers were predominant throughout a considerable area on the left bank of the river, and that their influence was felt for more than a century. The pagination remains the same as that of the two earlier editions of the book.

The Local Distribution of Electric Power in Workshops, &c. By Ernest Kilburn Scott, A.I.E.E. Pp. 137 + viii. (London: Biggs and Co.)

THE advantages of electric transmission of power in factories and workshops are not so well known as they might be, or the electric driving of machinery would be more extensively adopted than it is. Wherever electric motors have been made to do duty in machine shops, complete success has been attained, but it is only in late years that engineers and proprietors of factories have learned to make use of electric driving to any great extent. Lately, however, this branch of electrical engineering has been coming to the front, and it promises to develop into the most important branch of electrical work, electric lighting not excepted.

The information brought together by Mr. Scott will show manufacturers what has been done, and what electric motors are capable of doing. The advantages of electric driving, both economically and commercially, are clearly pointed out, and detailed particulars of power required by various machines are given. The advantages and disadvantages of alternating currents from the point of view of power distribution in factories are discussed, and there are descriptions of the various points of a power installation, with examples of the most recent practice. The book is thus one which should be in the hands of all who are concerned with the applications of electricity to the machines and tools of workshops and factories.

Memory and its Cultivation. By F. W. Edridge-Green, M.D., F.R.C.S. (International Scientific Series.) Pp. 307. (London: Kegan Paul and Co., Ltd., 1897.)

DR. EDRIDGE-GREEN considers that the human mind is divisible into "ultimate faculties," a list of which he gives. Of these "ultimate faculties" some thirty-seven are assigned to this position with certainty. Dr. Green has no doubt whatever about their fitness to be considered "ultimate faculties," although amongst them are such qualities as Causality, Alimentiveness, and Inhabitiveness. Others there are, such as Vitativeness and Human Nature, whose position as ultimate faculties of the human mind is still *sub judice.* Dr. Green might, we think, have postponed the publication of this book until he had made up his mind about them. Part of the book is devoted to the description of a system of cultivating the memory; but there is the best possible evidence that either Dr. Green does not himself utilise this system, or the system is worthless. He would certainly never have published a work on psychology without acquainting himself with the present state of knowledge upon the subject. Yet he has forgotten the whole of his psychological studies as completely as if they had never existed. If his system were one for cultivating the art of forgetfulness, and were a perfect system, the result could not be more complete.

Illusions and Hallucinations. By Edmund Parish. Pp. xiv + 390. (London: Walter Scott, Ltd., 1897.)

THIS is a very thorough account of the subject, in fact it is, perhaps, for the series to which the book belongs, almost too thorough, and the general reader may find some difficulty in getting a clear account of the author's views out of the mass of detail. The conditions of fallacious perception are fully considered, and the general phenomena are referred to disturbed association. The author gives new definitions of illusion and hallucination, the former being supposed to depend on the suppression of certain processes which normally intervene between the immediate sensory change and the perception process, while hallucination is referred to forced association. These definitions have the advantage that they refer both phenomena to a common cause, *i.e.* to dissociation of centres normally acting together; but they are open to the objection that they are based on purely theoretical and uncertain views, and it would probably be better to retain the old definition depending on the existence or non-existence of an external stimulus while recognising that there is no hard and fast line between the two conditions. There are two interesting chapters on the results of the international census of waking hallucinations. The author brings forward much evidence that the real nature of the "waking state" in most cases was one of abnormal dissociation. He criticises adversely the evidence for telepathy derived from the census, which was regarded as valid by the authors of the English Report. He brings forward from the Report itself evidence against this conclusion, and in regard to the supposed positive evidence, he lays great stress on the importance of similarity of association of ideas in the two cases. Among many other interesting points, only one can be mentioned here, viz. the criticism of the view that the negative hallucinations of hypnotism depend on suggested inattention. The author points out that an object may be made by suggestion to appear smaller and smaller, till it finally disappears. In this case, according to the theory, a phenomenon due to concentration or special direction of attention would be suddenly replaced by one due to lack of attention.

Transactions of the Rochdale Literary and Scientific Society. Vol. v., 1896-97. Pp. 90 + xxii. (Rochdale: James Clegg, 1897.)

BY publishing the papers in this volume the Council of the Rochdale Literary and Scientific Society brings the work of the Society into prominence, and assists in making the objects of the meetings known to a wider circle. The volume is as interesting as its predecessors, and is a creditable addition to local literature and science. Among the papers contained in the volume is a chatty account of "Men and Manners in Manila," by Dr. A. Jefferson, an elementary description (with figures) of "Egyptian hieroglyphics, picture-writing, and the English alphabet," by Mr. C. Heape, a brief note on some graphite and flint implements found in a neolithic store near Rough Hill, by Mr. W. H. Sutcliffe, and a paper on the geological history of the Cephalopoda, by Mr. Charles Wardingley.

We see from the report that a number of other papers, not included in the present volume, were read before the Society during the nineteenth session, and several very instructive lectures were delivered. The Society, appears, indeed, to be a centre of light and leading in Rochdale.

Les Constantes Physico-Chemiques. By D. Sidersky. Pp. 207. (Paris: Gauthier-Villars et Fils. Masson and Cie.

M. SIDERSKY has already contributed a volume on polarisation and saccharimetry to the Aide-Mémoire series in which the present book appears. The constants herein described are dealt with in a similar manner; they include density, change of state, viscosity, capillarity, indices of refraction, calorimetry, and photometry. For each of these constants, the author briefly describes the most exact and convenient methods of determining them, and gives in tabular form the results of observations made on various substances. In the descriptions of methods of experimentation, preference is given to those which are actually used in practice outside the physical laboratory, so the book will be a real aid in technical work. Physicists and physical chemists will find the volume a handy epitome of methods and results.

By Roadside and River: Gleanings from Nature's Fields. By H. Mead Briggs. Pp. 204. (London: Elliot Stock, 1897.)

"THE hand of destiny has scattered broadcast through the land the seeds of hope, and yet how many of them all have reached the harvest of ambition." If we rightly understand the purport of these opening words of the preface, the author is expressing some anxiety as to the fate of his literary efforts, and wondering whether his work will be appreciated. We wonder also what becomes of the host of books like this one, well printed and daintily produced, but amorphous in structure, and having no particular aim. There are, we suppose, people who enjoy reading insipid remarks based upon casual observations of nature, and to their kind attention we commend this book. A scientific mind soon wearies of trying to pick out the slender threads of fact which meander through the mass of sentiment.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Dugong.

IN the Hakluyt Society's last book, "The Christian Topography of Cosmas, an Egyptian Monk" (London, 1897), there are some interesting notices of "Indian Animals" with figures, copies of those in "the Florentine Codex"; which, in their turn, *may* have been "drawn by Cosmas himself (or under his direction)," according to an excellent modern critic.

In one passage Cosmas says "the flesh of the turtle, like mutton, is dark-coloured; that of the dolphin is like pork, but dark-coloured and rank; and that of the seal is, like pork, white and free from smell."

For reasons too long to give here, I suppose Cosmas' "seal" (phoke) to be the dugong; (halicore), which is generally described as very eatable; but I cannot anywhere find its colour, as meat, described.

"Potted dugong" from Queensland was on the London market not long ago; and I tried it, once. It was much of the colour of potted tongue.

The figure is more like a conventional sea-horse than anything else, and cannot be relied on much. It is, perhaps, a little less unlike to a dugong than to a seal.

The confusion of dugongs with seals still exists amongst seamen; though, of course, dying out amongst officers.

W. F. SINCLAIR.

Potato-Disease.

IN the "*Life and Letters of Charles Darwin,*" Darwin writes as follows:—

"Mr. Torbitt's plan of overcoming the potato-disease seems to me by far the best which has ever been suggested. It consists, as you know from his printed letter, of rearing a vast number of seedlings from cross-fertilised parents, exposing them to infection, ruthlessly destroying all that suffer, saving those which resist best, and repeating the process in successive seminal generations" (vol. iii. p. 348).

Can any of your readers inform me whether the plan was ever carried out, and if so with what amount of success?

Newcastle-on-Tyne, December 11. G. W. BULMAN.

THE PREVENTION AND CURE OF RINDERPEST.

IN the second fortnightly number for October of the *Agricultural Journal* of the Cape of Good Hope is given a long report of a Conference between the Hon. Mr. Faure, Minister for Agriculture, Mr. Hutcheon (C.V.S.), Dr. Turner, Dr. Edington and Dr. Kolle on the question of inoculation against rinderpest. This account is followed by the Resolution of Conference, by a letter from Dr. Edington and by one from Mr. Hutcheon, in the latter of which is given a review of the different methods of inoculation now used for the purpose of obtaining a certain degree of immunity against rinderpest in the cattle of South Africa. As so many different statements concerning the exact methods used at the Cape by Koch, by Edington, and by Turner and Kolle, and also by Messrs. Danyz and Bordet, have been promulgated, a summary of these various methods may be of interest.

In Koch's method of using the gall obtained from sick animals as a protection against rinderpest, the bile is taken from animals that have contracted the disease by natural infection. It was at first recommended that only green bile and bile free from blood should be used; later this recommendation was modified by Drs. Turner and Kolle, who say "that the difficulty of obtaining good bile has been much exaggerated. If the animals destined to produce immunising gall are injected with a small dose of really virulent blood, say 1 c.c., and are killed at the end of the sixth day of the fever, at least four out of five will give typically good galls, and the gall of the fifth will, in all probability, be fit for use. As a matter of fact, all galls which do not smell, and which are not absolutely red from the presence of a large quantity of blood, can be used without danger by Koch's process"; it is afterwards stated that those galls which have the highest specific gravity appear to possess the highest immunising power. It would appear, however, that the gall-produced immunity is only temporary, and that before long the animals again become susceptible to infection by rinderpest. Another of the great drawbacks to this method of inoculation is the fact that in certain cases the galls appear to contain septic organisms, which not only diminish the immunising power of the gall, but also in some instances seem to have set up a septic condition in the cattle injected.

Applying the method now in vogue in connection with the preservation of vaccine lymph, Dr. Edington added a quantity of glycerine to the gall with the object, first, of preserving for some time the gall in a pure condition, and, secondly, of killing any septic germs which might be present in the gall before it was drawn off from the gall-bladder of the infected animal. Of course it was necessary to use a somewhat larger quantity of this mixture in order to produce immunity. Dr. Edington injected from 15 to 25 c.c. into the subcutaneous tissue of the dewlap. Animals so protected when injected with small quantities of virulent blood, certainly appeared to take the disease in a milder form; in some cases this was accompanied by local reaction and by a rise in temperature, and wherever this occurred there was a marked degree of active and more lasting immunity conferred on the animal. When $\frac{1}{8}$th of a c.c. of virulent blood—that is, blood taken from an animal suffering from an acute attack of rinderpest—was injected, a local reaction was, in most instances, obtained, but in certain cases the preliminary temporary immunity was so slight, that the animal succumbed to the disease set up by the second injection. If, on the other hand, only $\frac{1}{10}$th of a c.c. was used, the local and constitutional reaction was not always obtained, and although a much smaller number of animals succumbed to the contracted disease, a much larger proportion remained susceptible to natural infection. In connection with this bile method, also, it must be pointed out that when the raw or unglycerinated gall was used as the protecting medium, a certain small proportion of cases contracted severe and even fatal attacks of rinderpest; though whether this was due to the gall itself or to the accidental contamination with virulent blood is not stated in the report, though we should imagine that this latter accident might be by no means uncommon.

Finally, there is the method based on the use of the "anti-bodies" found in the blood of salted cattle, *i.e.* cattle that have suffered from a severe attack of the disease, but have recovered. By injecting gradually increasing quantities of virulent blood into such animals, the anti-bodies appear in still larger proportions in the blood, and can then be used either in the form of a serum solution or as a defibrinated blood solution. This serum may be used to confer such a degree of passive immunity on the animal, that it either escapes the disease altogether, or contracts it in a much modified form; again, the serum may be used to cure an animal in which there is already a rise of temperature accompanied by other signs of a naturally acquired attack of rinderpest.

All these methods have now been used at the Cape, and it may be of some interest to our readers to learn what is the consensus of opinion as laid down in the Resolution of Conference. It is agreed "that inoculation with bile, either pure (Dr. Koch's) or glycerinated (Dr. Edington's), should not be adopted in any district in which it has not already been commenced, as more satisfactory and more permanent results are obtained from the use of serum, and the latter method can be more successfully applied in clean herds than in herds which have been previously inoculated with bile."

The "Conference" then arrive at the conclusion that it is better not to recommend that the inoculation with Koch's bile should be followed by an inoculation with virulent blood on the tenth day, as formerly recommended, as it is found that unless this blood inoculation is followed by a decided reaction—which occurs very rarely—the immunity already conferred by the bile is not increased. It is recommended, however, that in the case of dairy cattle which have already been inoculated with Koch's bile a second bile inoculation may be made, as this will confer a protection for several months, and at the same time will not interfere with the secretion of milk.

The glycerinated bile method should be followed on the tenth day by the inoculation of one-tenth of a c.c. of virulent blood; and although a second blood inoculation fourteen to seventeen days later increases the active immunity in certain cases, its use has been followed by considerable mortality, and the Conference, while not opposing a second inoculation of blood, does not recommend its universal adoption, as it is attended with considerable risk.

There appears to be a decided opinion that serum, when properly prepared, is superior to, and much more convenient for use than defibrinated blood, and its use is strongly recommended in preference to the latter when it can be obtained, though it is also recommended that a certain number of fortified salted cattle —*i.e.* immunised cattle—be sent to districts far removed from centres where serum is prepared, in order that defibrinated blood may be prepared in cases of sudden emergency.

It seems to be the general experience (as in other diseases in which the serum treatment is used) that in healthy herds the use of serum alone does not confer a very permanent immunity; it is therefore considered necessary, in infected districts, to infect healthy animals with rinderpest, and keep the attacks under control by means of the serum. This may be most safely and satisfactorily accomplished by injecting virulent blood subcutaneously on one side of the animal, and serum on the other. If necessary, *i.e.* if the disease takes too active a form, a fresh dose of serum will usually enable the animal to pull through the attack. For all practical purposes, however, it has been found that clean herds, in which there is no disease already, should not be inoculated with serum until the disease makes its appearance amongst them, or in their immediate neighbourhood. The whole of the animals should then be injected, after which, or simultaneously, they may be injected with virulent blood, or be kept in close continuous association with infected animals by kraaling them together every night. In this way the animals become salted or protected; under these conditions the immunity produced is active and of long duration, as opposed to the temporary and passive immunity that is conferred by serum when used alone, and perhaps also by bile. Where bile has already been inoculated, it is no use to inject serum and then virulent blood; for, as already mentioned, the immunity conferred by the bile varies very greatly in degree in different cases. Where such bile inoculation has been resorted to, the most satisfactory course for the owner to pursue is to keep a supply of serum by him and inject all cattle as soon as they are observed to be ill, or as soon as the thermometer indicates a rise of temperature. Where serum cannot be obtained, as already mentioned, the blood from salted cattle may be used. These salted cattle are usually fortified by injections of virulent blood, commencing with 10 c.c., and then going to 20, 50 and, lastly, 100 c.c. at intervals of ten days. Either serum or blood is injected in quantities of 100 or 200 c.c. into the animals suffering from the disease. This injection may be made subcutaneously, and not into the muscles, either behind the shoulder or into the dewlap.

It is, perhaps, too early to be dogmatic on the question of the best method of treating cattle for the prevention and cure of rinderpest, but when the exceedingly fatal nature of the disease is borne in mind, and when it is remembered that the disease is so markedly infective and fatal that whole herds are practically exterminated when once the disease is introduced (the objections that are brought forward against inoculation against anthrax, that the percentage mortality from inoculation is almost or quite as great as the percentage mortality from the disease itself not holding good in this case), it is not to be wondered at that the South African farmers received with enthusiasm any method which would preserve to them even a large percentage of their cattle, and that many of them were quite willing to run the risk of introducing rinderpest through the bile inoculation if they could only be sure that some 60 or 70 per cent. of the so infected animals would recover, and would then be protected to a certain degree against future attacks.

As Koch's bile method complied with such conditions it was undoubtedly a marked step forward, whilst it also made it possible to obtain salted cattle with which serum experiments might afterwards be carried out.

These serum experiments—showing that in serum the veterinary surgeon has in his hands a weapon by using which he is able to control the course, even of a severe attack of rinderpest—have given the farmers confidence enough to make them actually anxious to produce the disease under such conditions that they may keep it under control, and so salt their cattle artificially; thus rendering them immune for a considerable period against infection, even of the most virulent character.

With the vast agricultural and cattle-breeding interest at stake, we may anticipate that Koch's earlier experiments will, in the very near future, be improved upon, that South African cattle raisers and dealers will in the long run be enormously benefited, and that a source of wealth, which until a very short time ago was threatened with almost immediate extinction, will continue to be one of the principal resources of a great and flourishing colony.

LARGE REFRACTING AND REFLECTING TELESCOPES.

THE Yerkes Observatory, which has recently been completed and inaugurated, contains in its instrumental equipment the largest refractor in the world, the diameter of the object-glass spanning 40 inches.

The late Mr. Alvan Clark, the constructor of the lens in question, expressed the hope that still larger apertures might be successfully made, but he pointed out that the effect of flexure in larger discs was to be mostly feared, although he felt that it might be perhaps possible to still further increase the aperture without endangering the performance of the objective. Being therefore apparently near the limit to which such large object-glasses can be successfully constructed and mounted, it is only quite natural that attention should be turned to the other form of telescope, namely the reflector, and inquire whether this type of instrument is restricted in the same way as the refractor, or whether it can step beyond these bounds and open up fields which would otherwise be lost to us.

Discussions as to the capabilities of these two types of telescopes have been very rife, and while some observers hold that the reflector is the instrument of the future, others again take the other side and advocate refractors. It is now generally conceded that for definition the refractor is the instrument *par excellence*, but for purposes where light-grasping power is the main requirement the reflector takes the first place. In the cases of very large apertures reflectors can be made of diameters far exceeding anything that can be attempted for refractors. A point of initial importance in large instruments is the question of the focal length of the object-glass or mirror, as the case may be, for on this factor depends the length of the telescope tube. Now if this be of considerable length, the telescope mounting and dome have to be of considerable proportions, rendering the instrument both expensive and subject to many possible errors. To retain the size of the aperture of the instrument and reduce the focal length is a natural means of overcoming this difficulty, and this has been attempted in many instruments. Such a reduction is, however, accompanied by several optical drawbacks which detract from the efficiency of the instruments.

In the case of reflectors of large aperture and very short focal length a most striking deficiency becomes apparent, and, curiously enough, this has practically been passed unnoticed until Prof. Schaeberle (*Astr. Journal*, vol. xviii. No. 413) quite recently brought attention to it. So large is this source of bad definition, that he refers to it as a "fundamental optical defect." How he came to alight on this source of blurring factor will be best gathered from the following brief extract in his own words.

"On a very favourable night, I recently had the opportunity of testing the great Crossley reflector of the Lick Observatory, and found the surface of the same to be a practically perfect paraboloid of revolution; but on examining certain celestial objects—Saturn among others—I was very much surprised to find that the instrument failed most signally to come up to expectations. While puzzling and pondering over the probable cause of the poor results given by what I knew to be a finely figured surface, it occurred to me to ascertain the exact amount of the error introduced in the form of the image, resulting from the well-known fact that the focal point is not at the centre of curvature of the parabolic mirror."

To understand the origin of this bad definition, one must imagine a small circular disc situated in the focal plane of the paraboloid of revolution, and concentric with the optical axis. Viewing this disc from different points on the surface of the mirror, it is obvious that it will appear circular only when the eye is in the optical axis, but in all other positions it will appear elliptical, the eccentricities of the ellipses becoming greater the further the eye is moved away from the optical axis. Further, the angular diameter of both axes of the disc will decrease as the eye moves away from the optical axis, in consequence of the increase in distance from the focal point. The result of such a source of error as this would be that if the rays from the components of a double star be reflected by the mirror, the linear distance between their focal images as formed from different areas along any radius of the mirror will vary from a minimum for the area on the optical axis to a maximum for that area furthest away. In the case of a planetary disc, there will be produced a blurring effect caused by the numerous images of different sizes overlapping one another.

Having investigated this source of error, Prof. Schaeberle made a comparison of the efficiency of the more prominent reflectors now in use. The result is of such interest, that we must refer to it at some length.

In the following table the blurring effect for each mirror is tabulated in the fourth column, the fifth and sixth columns representing the computed difference of angular diameters of the outer ring of Saturn and the solar or lunar disc based on the given ratio of diameters.

Reflector	Diam. of mirror $= 2R_m$	Focal length $= F$	Max. ratio of diameters $= \frac{d}{r}$	Diff. of angular diameters for the given ratio		Limiting radius of field for best definition
				Saturn's outer ring	Sun or moon	
	Feet	Feet		″	″	″
Lord Rosse	6·0	55·0	1·0033	0·13	6	15
Common	5·0	27·0	77	0·31	14	7
Lassell	4·0	37·0	22	0·09	5	22
Melbourne	4·0	28·0	39	0·16	7	13
Paris	3·9	23·4	51	0·20	9	9
Crossley	3·0	17·3	57	0·23	10	9
Draper	2·4	13·0	64	0·26	12	8
Lassell	2·0	20·0	19	0·08	3	25
Roberts	1·7	8·2	78	0·31	14	6
Common	1·7	3·7	404	1·62	73	1
Schaeberle	1·5	12·3	28	0·11	5	19
Draper	1·3	13·0	19	0·08	3	25
Schaeberle	1·0	3·7	141	0·56	25	4

The last column gives the values for the limiting radius of the field of view of best definition for each telescope, on the assumption that the radius of the field of measured distances with the optical axis as centre, does not exceed a value which would introduce an error of more than 0″·05. The most striking feature of this column is the smallness of the fields in the several cases mentioned which are not influenced by this error.

A glance down the fifth column brings out clearly the fact that the smaller the ratio of focal length to diameter of mirror, the larger the difference of angular diameter of the objects observed. Thus in the case of the Draper, Schaeberle, and the two Lassell instruments, where this ratio is comparatively large, about 9 : 1, the differences are small, while for the two Common mirrors and Schaeberle's 12-inch, where the mean ratio is approximately 4 : 1, the differences increase very rapidly.

Not only will this blurring effect, caused by these differences of angular diameters of the images, be notably increased as the focal length is decreased, but the greater diameter of the image, and therefore distance from the optical axis, will bring this defect more in evidence.

The main result of the investigation, summed up in a few words, is that large parabolic mirrors having a ratio of focal length to aperture less than fourteen to one are, as regards definition, "theoretically unfit for making observations of extreme delicacy." It may be mentioned that this defect does not mar the efficiency of such instruments for certain kinds of work, such as spectroscopic, bolometric, &c.

Thus it is gathered from Prof. Schaeberle's investigation that reflectors of large aperture must also be of correspondingly great focal length if the definition of the object to be observed is to be of the first order.

As refractors of large aperture are seldom made of such short focal lengths as are in question, it is unnecessary here to consider the effect of this source of bad definition.

Several interesting points with reference to the capabilities of large instruments have been brought prominently forward during the last few months, and may be appropriately referred to in this place. Thus Prof. Wadsworth (*Astronomical Journal*, vol. xviii. No. 414) has dealt with the efficiency of large refractors for visual observations of planetary details. He finds that from an optical point of view, it is a distinct advantage to increase the apertures of telescopes intended for visual use of planetary detail, such as fine linear markings, up to such a point where the atmospheric aberration will amount to about one-seventh or one-eighth period under the best conditions of observation. If this point be exceeded, then no advantage is obtained, the efficiency actually falling off; the tendency is for the faint lines under observation to be blotted out, instead of becoming more distinct. Indeed so sure is he of this, that he says the limit of efficient size is about reached between 30 and 35 inches, or the limit is very rapidly approached.

Another point of great importance *re* large apertures is that such telescopes cannot always be efficiently used unless the night be very fine and the air still. The well-known observer, Dawes, always used to judge the night by the aperture that could be employed. Thus he spoke of a one-inch night, two-inch night, up to an eight-inch night, this being the greatest aperture he possessed. As a matter of history, one may relate that a comparison of the drawings of Mars made by Sir Norman Lockyer with his six-inch refractor, and by Lord Rosse with his big reflector, showed that although both series were made at the same time, they displayed striking dissimilarities. Dawes, who had also made some valuable drawings at the same opposition, in discussing this question of dissimilarity, concluded that Lockyer's drawings were the more correct, since they were found to be exactly like those he (Dawes) had made, especially with regard to a certain marking which he had called the "double tooth."

Dawes, however, was no lover of large apertures, and on the occasion just referred to he was heard to repeat one of his favourite phrases, "What have the giants done?"

Apart, then, from the quality of the instrument employed, definition depends on the state of the atmosphere through which the light rays pass. On clear nights the question of the movements of the air is of the highest importance, and it is only on this movement that the aperture for any particular night can be gauged. In consequence of these air undulations, which vary in different currents from half an inch to several feet in length, the definition varies enormously.

In the case of a small aperture, and supposing the wave-length to be more than double the diameter of the object-glass, the image of the object under observation would only be bodily moved without confusion; for a large glass the image would be very considerably blurred.

Dr. T. J. J. See has recently (*Astr. Nach.* No. 3455) been making investigations on the sizes and movements of these aerial movements, and his paper on this subject indicates the importance of increasing our knowledge by more systematic study.

Thus it will be seen that in discussing the question of how large telescopes may be made to do useful work, a most important item to take into consideration is the locality in which they will be used. If such a spot be happily found, situated on a high plateau where the movement of the air is practically nil, then theoretically there seems no reason why apertures should be limited in size; but as such a condition as this is rarely if ever to be obtained, a limit is necessarily imposed on the diameters of object-glasses.

W. J. S. LOCKYER.

THE WOBURN ABBEY DEER.

FROM the difficulty of obtaining an adequate series of specimens, either living or dead, the deer are one of the groups of large mammals with regard to which our present state of knowledge is decidedly not up to date, comparatively little advance having been made since the appearance of the late Sir Victor Brooke's well-known synopsis in the *Proceedings* of the Zoological Society for 1878. Fortunately the noble owner of Woburn Abbey, who takes a great interest in animals of all kinds, is endeavouring to get together as complete a collection as possible of these beautiful and interesting ruminants, or rather of such kinds as experience shows to be best suited to withstand the vicissitudes of the English climate. With characteristic liberality the whole of the magnificent collection now assembled is accessible to zoologists interested in this group of animals, and by its means considerable additions have already been made to our knowledge thereof. From the extent of ground much larger numbers of specimens of the same species can be collected than is possible in the limited space available in the Zoological Society's Gardens in Regent's Park; and the conditions existing in a large country park are, of course, far more favourable to the well-being and display of the animals than is possible in London.

In the Regent's Park the larger kinds of deer, such as the American wapiti, are generally, from necessity, represented by only two or three individuals at a time, but at Woburn these and other species are assembled in herds of considerable size. And as deer are remarkable for their seasonal variations in coat and colour, it is in such manner only that a full grasp can be obtained of these periodical changes. A further advantage is the opportunity of seeing closely allied species or varieties either in the same paddock or in near juxtaposition; while the facilities for studying the habits of the animals are infinitely in advance of what is possible elsewhere.

For a long period of years the domain at Woburn has been a deer-park where large herds of red and fallow deer wander at their own sweet will; and the undulating wooded ground alternating with level expanses of excellent pasture, and the numerous lakes and ponds dotted over the latter area afford an ideal situation for all animals of this class. Such foreign species as adapt themselves easily to these conditions, and do not make themselves objectionable by developing habits of ferocity, are allowed to run at large in the open park. Among these are Père David's deer, of Northern China, the elk, the Virginian deer, and the Japanese and Manchurian sikas; while muntjacs and roe run wild among the coverts. Such an amount of liberty cannot, however, be permitted to many of the species on account of their dangerous propensities; while it is found convenient or necessary to afford more protection from the wind and weather to yet other kinds. But even in the case of species deprived of their full liberty, the amount of space accorded them is ample, and quite different from what is practicable in domains of smaller magnitude. The American wapiti, for instance, live in a "paddock" of about 150 acres, surrounded by an eight-feet iron fence; and in the same enclosure, as shown in our first illustration, run the various races of sambar, as well as some of the sikas, and various other small species. A small herd of American bison are also among the denizens of this enclosure. Hard by, in a paddock of but little inferior dimensions, is a magnificent herd of the Altai wapiti, a species first made known in this country by antlers obtained by the second Yarkand expedition in Kashgar, and described by Mr. Blanford. The herd includes the first living examples of this splendid species ever brought to this country, although visitors to the Zoological Gardens have now an opportunity of seeing an immature specimen. And it is not a little remarkable that a stag so well known in the Altai, where it is kept in a semi-domestic condition by the farmers, should so long have remained a stranger to the menageries of Europe.

Perhaps, however, the most generally attractive of all the enclosures is the one which may be called the Chital paddock, on account of its containing a large herd of the beautiful chital or Indian spotted deer. A most successful photograph of a group of deer feeding in this paddock, for which we are also indebted to Her Grace the Duchess of Bedford, forms the subject of the second illustration. In addition to numerous chital, easily recognised by their dappled coats, this photograph shows several examples of the true maral, or Caspian red deer, from the Caucasus, which are the largest animals in the photo. This deer, it may be observed, although often regarded as a distinct species, appears to be nothing more than a race, or sub-species, of the red deer of Western Europe. Of the other smaller animals in the group, a Virginian deer occupies the foreground on the left, while several mouflon, and at least one Indian antelope, or black-buck, are in the centre.

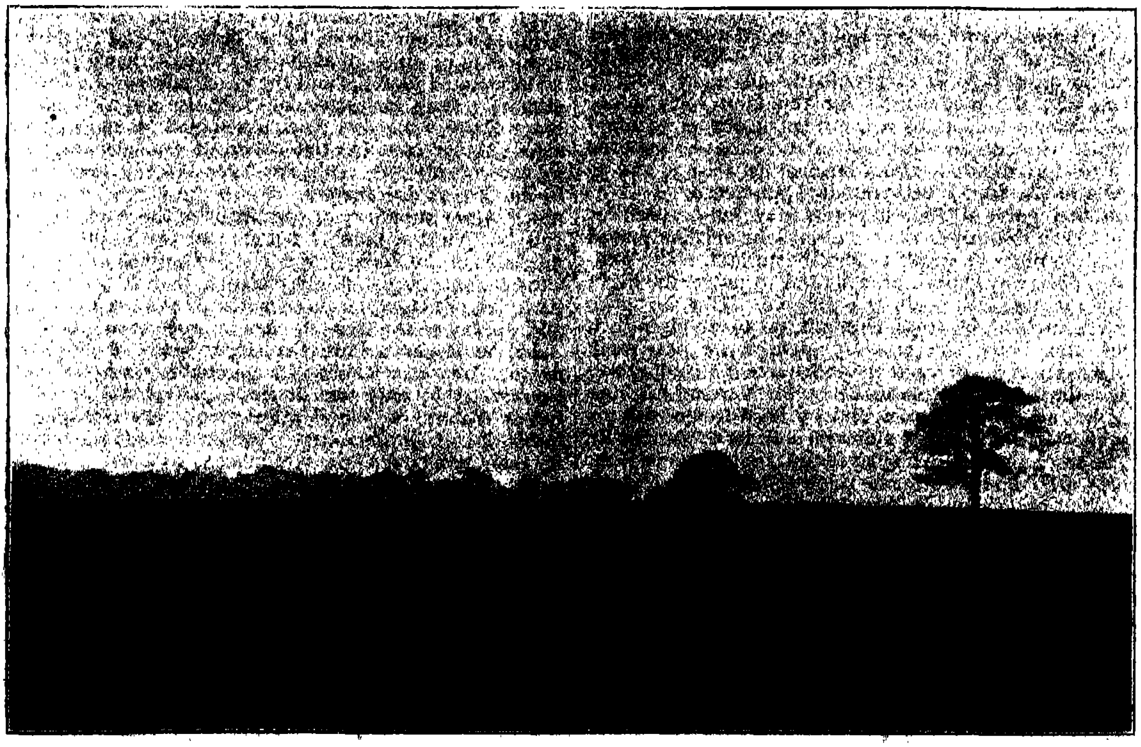

FIG. 1.—The American Wapiti Paddock at Woburn Abbey, showing Wapiti, Sambar, Sika, and Bison. (From a photograph by the Duchess of Bedford.)

From the torrid nature of their environment, it might have been supposed that the Indian chital and black-buck would have been among the species least suitable to withstand our climate. Nevertheless, this is not the case, and whereas these animals thrive and multiply at Woburn to an extraordinary degree, some northern species, like the elk and reindeer, which might have been expected to flourish best, die off in an unaccountable manner. Out of several head of American elk only a solitary survivor now remains, while all the adult reindeer are dead. Some young American calves of the latter species have, however, been recently received, and it may be hoped their fate will be happier. Possibly if Norwegian reindeer and elk were tried, they might do better than their American representatives. But it must be remembered that both these animals have disappeared at a comparatively recent date from Britain; and there may be something in our climate at the present time absolutely unfavourable to their existence.

The various Oriental races of sambar and rusa flourish at Woburn equally well with the chital, and the large series of these animals now collected there affords material for a fairly full study of an exceedingly difficult group. Hog-deer and muntjacs are also among those which are hardy and capable of acclimatisation. Other Oriental species represented in the collection are the swamp-deer of India, and the thameng of Burma and Siam; but these are kept in smaller and well-protected enclosures, with ample shelter. From the colder nature of their habitat, the various species and races of the sikas of Japan and Northern China might naturally be expected to do well, and as a matter of fact this has been found to be the case. In addition to the common Japanese and Manchurian sikas, the collection includes the large and handsome Pekin sika, previously known only by the type specimens sent home by the late Consul Swinhoe after the sack of the Imperial Summer Palace. Père David's deer has been already mentioned as among those running at large in the park, and there is good prospect of the herd of this aberrant and interesting species increasing in number. A solitary male of the previously imperfectly known Bedford's deer (*Cervus xanthopygus*) has unfortunately succumbed to a lingering decline, although happily not till it exhibited the remarkable variation between the summer and winter pélage. Roe deer, of course, flourish; and recently there was the opportunity of seeing the European, Siberian, and Manchurian species, or races, living side by side. The rare Chinese water-deer (*Hydropotes*) is represented by a single doe, which exhibits to perfection the skulking habits peculiar to the species; but a specimen of Michie's tufted deer, which formerly was one of the attractions of the collection, now adorns the museum at the Abbey. Musk-deer do not belie their hardy nature, and it is one of the most interesting sights in the park to watch these little deer bounding across their enclosure in the manner so well-known to all Himalayan sportsmen.

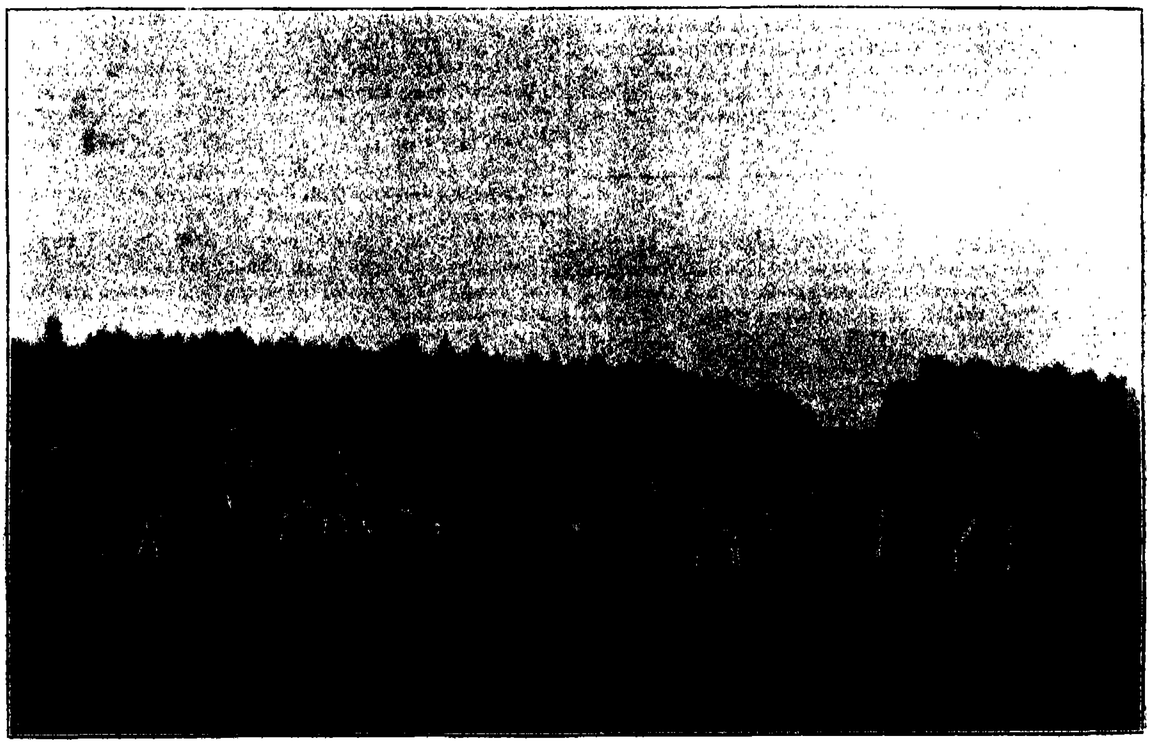

FIG. 2.—The Chital Paddock at Woburn Abbey, with Chital, Virginian Deer, Caspian Red Deer, Mouflon, and Black-Buck. (From a photograph by the Duchess of Bedford.)

In marked contrast to the adaptability of the Oriental deer to their new surroundings is the ill-luck attending the introduction of most of the American deer, exclusive of the wapiti. The only exception to this is the Virginian deer, which flourishes and breeds, some mingling with the chital herd, others roaming at will in the open park, and a few taking up their abode in the immediate vicinity of the Abbey itself. These latter exhibit tameness and fearlessness to an extraordinary degree—only, indeed, exceeded by the members of a little herd of roe from the Caucasus, one of which permits itself to be fondled like a pet lamb. Black-tailed and, we believe, mule-deer have been tried without success; while the same ill-fate has attended several examples of the South American marsh deer and pampas deer. Young examples of each of these two latter are, however, at the present time in the collection, and as they are very carefully tended, and the experience derived from their predecessors is available, it may be hoped they will survive. A tiny little deer, apparently referable to *Mazama gymnotis*, is also among the newest arrivals, and its career will naturally be watched with deep anxiety. Brockets have been tried with hopeless ill-success, and the attempt to acclimatise them has reluctantly been abandoned.

During the very short period the collection has been in existence it has included, counting red and fallow deer, close on forty distinct species and races—no mean record when it is remembered that the total number of valid forms which have been exhibited in the London Zoological Gardens since its foundation does not exceed forty-eight. As every effort is being made to increase the Woburn collection, it bids fair to beat the record in the number of species, as it already does in individuals.

R. L.

THE LATE PROFESSOR A. SCHRAUF.

THE comparatively small number of mineralogical workers and teachers has been once more diminished, and to the recent deaths of Mallard, Daubrée, DesCloizeaux, Sohncke, Retgers, Kenngott, Haughton and Heddle, must now be added that of Albrecht Schrauf, Professor of Physical Mineralogy in the University of Vienna, who has passed away, after long illness, near the end of the sixtieth year of his age. A. Schrauf was born on December 14, 1837; he became assistant in the Mineral Department of the Imperial Museum of Vienna in 1861, and Keeper in 1867; after

1862 he added to his Museum duties the work of a "Docent" in the University; but eventually (1877) retired altogether from the Imperial Museum to take upon himself the duties of the University Professorship, involving the care of the University Mineral Collection: in this office he remained till the end of his life.

Much of Schrauf's published work consists in the technical examination and description of mineral species, but he also gave much thought to the general and recondite problems connected with atoms and molecules and their relation to the physical characters of crystals: his earlier speculations are incorporated in his "Treatise on Physical Mineralogy" published in 1866-68, but the later are only to be found in isolated memoirs. He was also the author of a useful handbook on "Precious Stones" (1869). Interested deeply in the philosophy of his subject, he sought the necessary mental and physical relaxation in the mechanics of crystal drawing, and undertook to prepare for publication an Atlas of the crystalline forms of all mineral species, taken in alphabetical order: but species and forms were discovered more quickly than figures could be prepared and sold, and the publication was discontinued before the letter D had been arrived at. The loss of a real thinker is a great one for any science.

NOTES.

Among those who have accepted nomination as vice-presidents of the general committee of the Fourth International Congress of Zoology are the following:—Prof. R. J. Anderson, of Belfast; Prof. Bridge, of Birmingham; Prof. D. J. Cunningham, of Dublin; Prof. Herdman, F.R.S., of Liverpool; Prof. M'Intosh, F.R.S., of St. Andrews; Mr. J. Cosmo Melvill, of Manchester; Prof. Lloyd Morgan, of Bristol; Prof. Alleyne Nicholson, F.R.S., of Aberdeen; Dr. Scharff, of Dublin; Dr. Traquair, F.R.S., of Edinburgh; Canon Tristram, F.R.S., of Durham; Lieutenant-Colonel R. G. Wardlaw Ramsay; and Prof. Percival Wright, of Dublin.

Mr. George Sharman retires at the end of this year from the post of Palæontologist to the Geological Survey of Great Britain. Entering the service just before the death of De la Beche in 1855, he served for a while under the first Director-General, and subsequently under Murchison, Ramsay, and Sir Archibald Geikie, with Mr. J. W. Salter and Mr. R. Etheridge as his senior colleagues. On the retirement of Mr. Etheridge in 1881, he was promoted, together with Mr. E. T. Newton, to take charge of the palæontological collections in the Museum of Practical Geology. Although he has published but little outside the "Memoirs of the Geological Survey," Mr. Sharman has sedulously devoted himself to the study of British fossils, and more especially the Invertebrata, his acquaintance with which is unequalled. The important aid which he has continuously given for over forty years to the field-geologists of the Survey is shown to some extent in the lists of fossils published in the official "Memoirs"; but no inconsiderable portion of his time has been given to those inquirers who so frequently come to a public museum with bags and pockets full of fossils to be identified by the officers. His skill and patience, and his readiness to give information have combined to characterise his long career as one of marked and unselfish devotion to the public service.

The death is announced of Prof. Wilhelm Joest, known by his travels in North Africa, America and Asia.

Mr. Henry Cecil, writing from Bournemouth, under date December 24, says:—"I was fortunate enough to see, at 1.13 this morning, in the middle of the latter half of its passage, the most remarkable meteor I ever saw. At that hour the sky was perfectly clear; and looking at the brilliant stars through the western of two windows looking south, I became suddenly aware of an intense white illumination overhead, which, from the steepness of the arc, could not, I think, have had its origin far to the westward of the zenith."

In the course of an article upon Sir W. E. Garstin's report on the work of the Irrigation Department of Egypt in 1896, the *Times* mentions as a new indication of scientific progress in Africa, that, since January 1, 1896, the water levels of the Victoria Nyanza have been daily recorded by means of gauges erected at three places, viz. Port Alice, Port Victoria, and Lubwas Usoga. The readings, as also a monthly statement showing the rise and fall of the lake, are received at Cairo; but the records of a series of years are necessary before any attempt can be made certainly to prognosticate the extent of influence that a rise or fall of the lake waters may produce on the Nile. The report states that gauges upon the Albert Nyanza are very urgently required in order to show what are the relations between the levels of that lake and the summer water supply in Egypt. This lake being nearer to the point of delivery, its levels are, if possible, more important to Egypt than are those of Lake Victoria, and the hope is expressed that the English officials at Uganda may erect gauges and furnish Egypt with records of the daily readings. Major R. H. Brown, Inspector-General of Irrigation for Lower Egypt, in his report for 1896 expresses the opinion that, as the catchment area of Lake Victoria is comparatively small, the lake may not have such an important influence on the Nile as we are accustomed to attribute to it, and that gauges at Fashoda, Khartum, and Berber are what is chiefly wanted.

We are glad to see that a Lincolnshire Science Society has been established. For many years there has been, in Lincolnshire, an absence of combination among scientific workers. Of individual investigators there is no lack, and much valuable work has been carried on by them; but from a want of knowledge of what has been, and what is being done by others in the special subjects in which each is interested, there has been a waste of time and energy. A central, organising, directive force has been wanting; and it is to supply this want, and to give to individuals and to the local county societies an opportunity for combining forces for the purpose of centralising and directing their efforts so that their various plans of action may be harmonised, that the Lincolnshire Science Society has been called into existence. The Society consists of a number of sections, the members of each of which devote themselves to the working out of one or more lines of research in the sciences that the sections represent. The presidents of the sections form the Council of the Society, and it is a part of their duty to suggest to the members and to the affiliated societies such lines of research and such methods as will be likely to yield the best results. The Society is at present actively helping on a scheme having for its object the foundation and the endowment of a county museum. The object is a worthy one, and we trust that both it and the Society will meet with the fullest encouragement and success. Particulars referring to the Society may be obtained from the president, Dr. G. M. Lowe, the hon. sec., Mr. G. Grierson, or the vice-president, Mr. J. H. Cooke, Thorndale, Lincoln.

A fresh contribution to our knowledge of the physiological effects of high altitudes is given by Prof. Piero Giacosa (*Rendiconti del R. Istituto Lombardo*, xvii.), who has studied more especially their influence on the exchange of material, and, particularly on the elimination of nitrogen. Prof. Giacosa considers that as the altitude of 6000 metres is approached, there is an increasing risk of reaching the limit beyond which the physiological functions cannot be completed; but below 6000 métres the diminished pressure is never a direct and sufficient cause of the disorders that are observed, and its only effect is to aggravate those due to fatigue, to impaired digestion, and to other causes.

WRITING in the *Memorie della Società degli spettroscopisti Italiani*, xxvi., Dr. G. B. Rizzo publishes the details of a number of observations for determining the value of the solar constant. This value could not be determined with sufficient accuracy from experiments made at one station alone, as it was found that the results varied largely according to the formula employed; observations should therefore be taken at several stations differing considerably in altitude, but at no great horizontal distance apart. Four stations were therefore selected on Monte Rocciamelone, in the Val di Susa, at altitudes of 501, 1722, 2834 and 3537 metres, and by determining the intensity of solar radiation, referred to the zenith, at these stations, the relations between this intensity and the corresponding atmospheric pressure were expressed by means of two independent empiric formulæ. From these the author finally infers that the solar constant has a value of approximately 2·5 small calories per square centimetre per minute.

MR. R. F. ARNOTT writes to us from Sĕlángor, Straits Settlements, with reference to a note on the alleged conversion of Mexican silver dollars into gold, by Dr. Stephen H. Emmens (September 9, 1897, p. 451). He has assayed four Mexican dollars in circulation at Sĕlángor, and found gold in appreciable quantity, as follows:—

Number of assay.	Marks.	Gold.
1.	8 R.G.^{A} 1874 I.G.	0·06 per cent.
2.	8 R.O.^{A} 1892 E.N.	0·09 ,,
3.	8 R.G.^{A} 1893 J.S.	0·08 ,,
4.	8 R.G.^{A} 1895 M.M.	0·01 ,,

The dollars were taken at random from rather more than a hundred different issues, and no unusual treatment was employed during assay. The results are worth putting on record, as they suggest a possible origin of the gold in the "argentaurum" manufactured by Dr. Emmens. It is, however, well known that gold exists in Mexican dollars. Our attention has been called to the fact that in 1891 an examination of 11,846 such coins was made at the Royal Mint (see Report of the Deputy-Master of the Mint for 1891, pp. 110–113). The dollars from all the Mexican mints were found to contain gold, the average amount being 0·309 per 1000. Those from Guadalajara (Nos. 1, 3 and 4 of Mr. Arnott) numbered 463, and contained an average of 0·964 of gold per 1000. In connection with the presence of gold in silver, Mr. Arnott points out that much of the silver received at the Indian mints some years ago was rich in gold; sycee containing an average of about 0·9 per cent., and silver coins issued contained as much as 0·09 per cent. of gold.

THE attention of the commercial interests of Germany has recently been directed to the great advantage that would be derived to the trade of that country by the completion of the canal system joining the Black Sea with the North Sea, and also with the Baltic. At present all merchandise conveyed to and from the East has to go round by sea to Hamburg or Stettin, the distance by sea being more than 3000 miles as compared with about 1000 miles through Austria and Germany by a system of inland waterways. Two Congresses have recently been held—one at Passau, in Bavaria, and the other at Vienna—for the study and discussion of schemes for developing this through communication, and the Ministry of Commerce at Vienna has had inquiries made as to the feasibility of the plans proposed. These are to open out and improve the Ludwig Canal, which connects the Danube with the Main, and so with the Rhine, so as to make it available for barges carrying 500 tons, and thus completing a direct water-way between the Black and North Seas. The length of this canal is 106 miles, and it now has a depth of water of only five feet and a navigation fitted for 127-ton barges. The second part of the proposed scheme is to connect the Danube with the Elbe by a new canal from the former, near Vienna, turning in a north-west direction to join the Upper Moldau, and by the canalisation of this river to Prague, and of the Elbe to Aussen. The third scheme is to connect the Austrian and German water-ways by connecting the March, an effluent of the Danube, with the Oder, and making the system capable of taking 600-ton barges, and thus connecting the Black Sea with the Baltic. The Russian scheme, having a similar object, and described in NATURE of February 25, is to be commenced forthwith.

THE latest issue of the *Memoirs* of the Caucasian branch of the Russian Geographical Society (vol. xvii. part 1), contains the first part of a very valuable work, by A. V. Voznesensky, on the precipitation in Caucasia. The author gives first a series of tables, for 113 Caucasian stations, showing the amounts of rain and snow, and the numbers of days with rain or snow, for every month of every year during which observations were made at each station. The position of each observatory—its latitude, longitude and altitude, the elevation of the pluviometer above the ground, and general remarks are also given; and at the end of the work the results are summed up in a general table. Sixteen maps accompany the work: one of them is an orographical map of Caucasia; then come two series, of five maps each, showing by curves the geographical distribution of precipitation over the territory, *i.e.* the average amount of precipitation, and the probability of snow or rain for the whole year and for each season separately. The distribution of precipitation during the different months of the year is next represented by diagrams for thirty stations; and seven different types having thus been established, the geographical distribution of the regions belonging to each of these types is given on a map. Another map shows the more or less uniformity which exists in the distribution of precipitation during the year in various parts of Caucasia; and two more maps represent by curves the regions of summer and winter droughts, as well as the intermediate regions. The text in which the general conclusions had to be discussed has been left for a second part of the same work, the author having had to leave the Caucasus to take up the management of a meteorological station at Irkutsk.

It is thirty-five years since the late Mr. S. P. Woodward described the remarkable fossil *Barrettia* from the Cretaceous limestone of Jamaica. Though in general appearance it resembled an operculate coral, Mr. Woodward came to the conclusion that it was really an aberrant Lamellibranch of the Hippurite group. Since that time nothing has been added to our knowledge of the form; but in a recent *Bulletin* of the American Museum of Natural History, Mr. R. P. Whitfield gives the results of his study of a large series of specimens obtained from the original locality, which show certain additional details of structure. He cannot agree that *Barrettia* was a Lamellibranch, but strongly inclines to place it among the corals: it certainly is a very isolated form, as the only corals with which he is able to suggest comparisons in structure are of Palæozoic age.

"Do the crystalline gneisses represent portions of the original earth's crust?" is the question asked, and answered in the affirmative, by Mr. J. Lomas, in his recent presidential address to the Liverpool Geological Society (published in the December *Geological Magazine*). Excluding gneisses of later igneous or metamorphic origin, there remain the great series of fundamental gneisses, world-wide in distribution and uniform in general character, which must have had some world-wide cause of origin. As a possible cause of their foliation, Mr. Lomas suggests tidal action in the incompletely-consolidated crust. Prof. G. H. Darwin has shown that huge tidal wrinkles must have been raised by the moon when near the earth, forming idges and troughs which ran north and south near the Equator, and curved to the eastward as they approached the Poles. The strike of the gneisses of Britain and Scandinavia corresponds to the direction of these tidal wrinkles in those latitudes, and there is evidence that the Palæozoic strata were deposited in troughs parallel to the gneissic ridges. In Anglesey, according to Mr. Lomas, we have a portion of one such ridge that may never have been submerged under the sea.

THE Cambridge University Press has just published a volume of "Solutions of the Exercises in Taylor's Euclid" (Pitt Press Mathematical Series), Books VI.-XI.

MR. H. TRIMBLE reprints, from the *American Journal of Pharmacy*, a series of papers by himself and the late Prof. E. S. Bastin, on "Some North American Coniferæ." Some of the more important American species from an economical point of view are described in detail, special attention being given to the microscopical structure of the leaf and stem and to the chemical composition of the wood. Excellent photographs are given to show the habit of each species, and woodcuts of microscopic sections.

A SECOND edition of Mr. Arthur Mee's "Observational Astronomy," greatly enlarged and improved, has just been published by the office of the *Western Mail*, Cardiff. The new edition is, in point of illustration, vastly superior to the original work, some of the half-tone blocks being very fine reproductions; the text also has been through the refining fire. The volume should be in the possession of every amateur astronomer, however limited his instrumental equipment may be; for it will bring him right into the current of astronomical thought, and inspire him to make the best use of his opportunities.

VOL. VIII., part 1, of the *Proceedings* of the Liverpool Geological Society contains a valuable series of papers. These include the presidential address on "Glacial Geology," and a paper on "Ayrshire Geology," by Mr. Mellard Reade; detailed and illustrated accounts of the "Carboniferous Limestone of the Clwyd Valley," by Mr. G. H. Morton; of the "Igneous Rocks of Aran Mowddwy," by Mr. T. H. Cope; and of the "Varanger Fjord," by Messrs. Dickson and Holland. Mr. Lomas investigates the earthquake of December 17, 1896, and traces the isoseismal lines; and Dr. Callaway criticises the chemical evidence for the existence of organisms in Archæan times, finding it quite fallacious.

THE Thornton-Pickard Manufacturing Company, Ltd., have sent us a copy of their new illustrated catalogue for 1898. Several very fine half-tone reproductions of photographs illustrate the catalogue, and testify to the excellence of results obtained with cameras and instantaneous shutters manufactured by the firm. Among the apparatus which call for special mention are a new 5 × 4 size of the Amber camera, a new patent film carrier, and a new aluminium shutter. The firm offers 200*l*. in prizes for the best results obtained with their cameras and shutters. Full particulars of this competition, as well as many serviceable hints to photographers, will be found in the catalogue, a copy of which will be forwarded on application.

WE have received the yearly report of the Russian Geographical Society for the year 1896, and it is full of interest. It contains, as usual, the obituaries of the members whom the Society lost during the year, condensed reports of the expeditions of the Society, a review of its publications, and excellent accounts of the work done by those geographers to whom medals were awarded by the Society in 1896. Very valuable feature of this year's reports are the yearly reports of the Siberian branch of the Society (Irkutsk) and of the Amur branch (Khabarovsk) for the years 1894 and 1895, as also of the Society for the Study of the Amur Region for the year 1895. Unfortunately, one does not find in the report any information concerning the extremely interesting but almost quite unknown activity of the West Siberian branch of the Russian Geographical Society.

A SECOND edition of Prof. J. J. Thomson's "Elements of the Mathematical Theory of Electricity and Magnetism" has just been published by the Cambridge University Press. The first edition, published in 1895, was reviewed in NATURE (vol. liv. p. 97), and as few alterations have been made, we need do no more than announce the appearance of the new edition, and express pleasure that the work is finding its way into the hands of an increasing number of students.—Prof. J. A. Ewing's work on "The Steam Engine and other Heat Engines" (Cambridge University Press), reviewed in NATURE three years ago (vol. li. p. 219), has also reached a second edition. A considerable amount of new matter has been added to the volume, and the section relating to gas engines has been much extended. To the thoughtful student of engineering science the book is invaluable.—Part 2 of "An Illustrated Manual of British Birds," by Mr. Howard Saunders, has been published by Messrs. Gurney and Jackson. The work will be completed in twenty parts, and will contain illustrations of nearly every species.

THE annual report on the work of the Institute of Jamaica has been received. The Science Section of the Institute appears to have been particularly active in the period covered by the report. A number of changes have been made in the systematic arrangement of the objects in the museum. In the zoological collection a 4 to 6 per cent. solution of formalin has been mostly employed as a preservative fluid and found to work very satisfactorily, though the colours of the objects were not retained for long in specimens exposed to strong light. For delicate objects, such as jellyfish and sea-anemones, it is found to be extremely serviceable, preserving perfectly the natural form and histology. Research work, mainly upon the Actinaria of the island, has been continued in the Biological Laboratory of the Institute. A paper on the Jamaica Zoanthidæ, embracing a description of ten species, has been prepared by the curator for publication; also one on the Actinian family Aliciidæ, describing, amongst others, a new Jamaica species of Bunodeopsis. During the summer months three students from the Johns Hopkins University, under the direction of Prof. Brooks, established a temporary marine laboratory at Port Henderson. Contributions to Jamaican zoology have been made by them, and many specimens were presented to the museum. Investigations of Indian remains have been continued from last year, and more valuable material collected from the caves and refuse-heaps. The objects, however, do not differ greatly in type from those referred to in the last report. An account of the results, illustrated with numerous figures, plates, and a map, will shortly be published in the *Journal* of the Institute. The report thus shows that the Institute is actively assisting in the advancement of knowledge, as well as working in various ways to create and stimulate interest in scientific objects and study.

IN the current number of the *Berichte*, P. Walden describes the very remarkable effect produced by the addition of a uranyl salt to a solution of an optically active substance. When a substance such as *l*-malic acid is dissolved in water along with one molecule of uranyl nitrate and about four molecules of caustic potash, the rotation produced by the solution is more than five hundred times as great as that of the acid alone, whilst it remains of the same sign. Similar, but less intense effects are observed with other optically active hydroxy-acids and their ethereal salts, but no increase is produced with optically active substances, such as chlorosuccinic acid, which do not contain a hydroxyl group, and indeed a slight diminution is caused in some of these cases. Optically inactive acids, such as mesotartaric acid, inactive malic acid, &c., are quite unaffected by the addition of these substances. Apart from its high theoretical interest, the phenomenon provides a ready method of distinguishing active substances of low rotatory power from their inactive isomerides.

THE additions to the Zoological Society's Gardens during the past week include a Chacma Baboon (*Cynocephalus porcarius*, ♂), a Black-backed Jackal (*Canis mesomelas*, ♀) from South Africa, presented by Major Haynes Sadler; a Red-bellied Wallaby (*Macropus billardieri*) from Tasmania, presented by Mrs. Beaumont; a Guillemot (*Lomvia troile*), British, presented by Mr. John Pettitt; a Yellow-cheeked Lemur (*Lemur xanthomystax*) from Madagascar, a Marsh Harrier (*Circus æruginosus*), European, deposited; six Summer Ducks (*Æx sponsa*, 5 ♂, 1 ♀), purchased.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN JANUARY:—

January	h. m. h. m.	
2.		Meteoric shower from Quadrans (230° + 52°).
3.	6 59 to 8 16.	Occultation of 16 Tauri (mag. 6·5).
3.	7 13 ,, 8 27.	,, 17 ,, 3·8).
3.	8 2 ,, 9 11.	,, 23 ,, 4·2).
3.	8 46 ,, 10 8.	,, η ,, 3·0).
3.	9 55 ,, 11 11.	,, 28 ,, 6·2).
3.	10 1 ,, 10 59.	,, 27 ,, 3·8).
5.		Uranus 52′ S. of β Scorpii.
5.	12 56 to 13 58.	Occultation of 125 ,, 4·9)
7.	10 57 ,, 12 32.	Partial eclipse of the moon. Magnitude 0·157 at 11h. 45m.
9.	8 11 ,, 9 8.	Occultation of o′ Cancri (mag. 5·2).
10.	15 53 ,, 17 4.	Occultation of B.A.C. 3398 (mag. 6·0).
14.	5	Jupiter in conjunction with moon. ♃ 7° 5′ N.
17.	16 30 to 17 31.	Occultation of B.A.C. 5314 (mag. 5·4).
17.	18 51 ,, 20 1.	,, ,, 5347 ,, 5·8).
18.	7	Saturn in conjunction with moon. ♄ 5° 40′ N.
18.	12 53 to 15 25.	Transit of Jupiter's Satellite III.
20.	8 31.	Minimum of β Persei (Algol).
21.		Total eclipse of the sun invisible at Greenwich. Begins on the earth generally 16h. 46m., ends 21h. 53m.
23.	5 20.	Minimum of β Persei (Algol).
25.	11 56 to 14 52.	Transit of shadow Jupiter's Sat. III.
25.	16 37 ,, 19 6.	,, Jupiter's Sat. III.
29.	4.	Mercury at greatest elongation (25° 4′ W.)

"NAUTICAL ALMANAC" CORRIGENDA.—In a letter to the *Journal* of the British Astronomical Association, Dr. A. M. W. Downing forcibly impresses upon astronomers the necessity and importance of consulting the page of *errata* in each issue of the *Nautical Almanac*. In consequence of the *Nautical Almanac* going to press four years in advance, any corrections to data influencing the tables gives, of course, slightly modified results. We read, for instance, that "in the first edition of the *Nautical Almanac* for 1898 (issued in December 1894) the data are affected by an error which throws out the times of the lunar eclipses to a considerable extent; in the second edition (issued last April), and in a subsequent edition, now being struck off, this error has been corrected. The correct data are also given amongst the *errata* on page xiii of the *Nautical Almanac* 1899. It will therefore be advisable for those interested in these phenomena, should they happen to possess the first edition of the *Nautical Almanac* for 1898, to correct the data for lunar eclipses in that edition by the *errata* given in the *Nautical Almanac* for 1899."

Another correction in the same edition is the position of 16 Tauri in the Pleiades, which makes an occultation of this star on January 3 a near approach only.

OCCULTATION OF THE PLEIADES.—For the third time in less than half a year the Pleiades will suffer occultation by the moon on January 3. As in the case of the occultation which took place last October, all the brighter stars will be occulted with the exception of 16 Tauri (see note on "*Nautical Almanac* Corrigenda"), and this star, although approaching very near, is just missed. The most interesting occultation will be that of Alcyone (mag. 3·0), the brightest star in the Pleiades, and its disappearance at the dark limb should be seen with the smallest telescope. The times are as follow:—

Time of disappearance, January 3d. 8h. 46m. G.M.T.
,, reappearance ,, 10h. 8m. ,,

The Iris Gulf will be in the neighbourhood of the terminator where the star disappears.

The passage of the moon before the Pleiades, although a beautiful phenomenon at any time, in this case loses some of its charm through the brightness of the moon, her age being nearly 11 days, and consequently the aërial reflection will overpower the fainter stars of this group.

PARTIAL ECLIPSE OF THE MOON.—That the moon is getting into position for eclipsing the sun on January 22 is announced by the fact that she herself is under partial eclipse at the preceding lunation on January 7. The phenomenon commences a little before midnight, and ends an hour and a half after.

The eclipse is a very small one, its magnitude being only 0·157 (moon's diameter = 1).

The following are the corrected phases as given in the *Nautical Almanac* (1898) (see note on "*Nautical Almanac* Corrigenda.")

		d.	h.	m.	
First contact with the penumbra,	January	7	10	1·2	p.m.
,, ,, ,, shadow	,,		11	47·4	,,
Middle of eclipse	,,	8	0	34·9	a.m.
Last contact with the shadow	,,		1	22·4	,,
,, ,, ,, penumbra	,,		3	8·6	,,

NEW INVESTIGATIONS OF β LYRÆ.—Prof. A. Belopolsky has recently completed a new series of photographs in connection with the spectrum variations of β Lyræ; and his paper on "New investigations of the spectrum of β Lyræ" appears in the *Astrophysical Journal*, November 1897. In all, twenty-six photographs have been taken corresponding to all the phases of brightness, and the results are especially interesting since an "iron comparison" has enabled him to determine the velocity of the system with respect to the sun, and also the radial velocities at different parts of the orbit.

The dark line at λ 4482 has been utilised in making all the measures, for this line changes but little in appearance, whilst the lines λ 4471, H_β and H_γ undergo great variations.

From measures made of the above line, with the iron comparison as datum lines, he finds that the proper motion of the system = −2·00 geographical miles, and the maximum radial velocity is about 25 geographical miles. Moreover, the curve of radial velocities shows that the changes of brightness may be sufficiently well explained by an *eclipse*; for the times of radial velocity = 0 are very close to the times of principal and secondary minima. His description of the cyclical changes which take place in the appearances of the lines at λλ 4471 and 4482, and the reappearance of certain additional lines at particular phases agrees remarkably well with the Kensington results, which, it may be remembered, showed that of the components producing the dark lines, one was like Bellatrix, and the other gave a spectrum similar to that of Rigel.

THE ATMOSPHERES OF PLANETS.—Dr. Johnstone Stoney's name has long been connected with an important theorem in molecular physics, which may be thus stated. The atmosphere round any planet will extend to a height determined by the force of gravity on that planet, and if the speed with which the molecules move in that atmosphere exceed a critical velocity, they will escape from the planet and move independently in space. In the *Transactions* of the Royal Dublin Society, November 1897, Dr. Stoney has given in some detail his full views on this subject, and substituted better numerical results for those originally given in scattered scientific papers, by basing them on the fact that helium, whose density is twice that of hydrogen, can, and does, escape from the earth. It is contended that helium is continually being supplied to the earth's atmosphere from hot springs, that it exhibits no tendency to combine with other elements, and since no trace of it can be found in the atmosphere, it escapes above, as rapidly as it enters below. Water vapour, on the other hand, remains on the earth, and consequently limits of speed can be assigned between which gases are either imprisoned or are free to escape. For the earth, under favourable circumstances, a velocity of 10·5 km. per sec. would be sufficient to carry a molecule beyond gravitational control, and this is 6·5 times the "velocity of mean square" in hydrogen gas at a temperature of – 66° C.; 9·27 times that of helium at the same temperature, and 19·66 times that of water vapour. Since the two former gases escape and the latter does not, it would seem that the velocity attained by molecules can exceed nine times the average velocity, but cannot reach that of twenty. Assuming that Venus retains a moisture-laden atmosphere, about which Dr. Stoney seems very positive, this latter number can be reduced to eighteen, and thus still closer express the actual velocity in terms of that of the "mean square."

Limiting the inquiry to a temperature of – 66° C., Dr. Stoney applies the theory to all members of the solar system with the following results. From the moon all gases having a vapour density less than 39 will escape with greater promptness than helium does from the earth. On Mercury, water cannot exist, while nitrogen and oxygen would gradually dribble away. The conditions on Venus resemble those on the earth, but the case of Mars is of exceptional interest. Dr. Stoney says that it is legitimate to infer that on this planet water cannot remain. The atmosphere he considers to consist mainly of nitrogen, argon, and carbon dioxide. He thinks there is no vegetation, as we understand the term, on the surface of the planet, and the snow, frost, and fog do not arise from the same cause as on the earth. Jupiter is able to imprison all gases known to chemists, but whether the more distant members of our system can retain hydrogen is doubtful. Helium and the denser gases probably float in their atmospheres, but the molecules of the lighter gases are describing orbits about the sun, the velocity they can acquire enabling them to escape from planetary control, but still insufficient to liberate them from the gravitational influence of the sun.

THE DENSITIES OF CERTAIN GASES.[1]

THE observations here recorded were carried out by the method and with the apparatus described in a former paper,[2] to which reference may be made for details. It must suffice to say that the globe containing the gas to be weighed was filled at 0° C., and to a pressure determined by a manometric gauge. This pressure, nearly atmospheric, is slightly variable with temperature on account of the expansion of the mercury and iron involved. The actually observed weights are corrected so as to correspond with a temperature of 15° C. of the gauge, as well as for the errors in the platinum and brass weights employed. In the present, as well as in the former, experiments I have been ably assisted by Mr. George Gordon.

Carbonic Oxide.

This gas was prepared by three methods. In the first method a flask, sealed to the rest of the apparatus, was charged with 80 grams recrystallised ferrocyanide of potassium and 360 c.c. strong sulphuric acid. The generation of gas could be started by the application of heat, and with care it could be checked and finally stopped by the removal of the flame with subsequent application, if necessary, of wet cotton wool to the exterior of the flask. In this way one charge could be utilised with great advantage for several fillings. On leaving the flask the gas was passed through a bubble containing potash solution (convenient as allowing the rate of production to be more easily estimated), and thence through tubes charged with fragments of potash and phosphoric anhydride, all connected by sealing. When possible, the weight of the globe *full* was compared with the mean of the preceding and following weights *empty*. Four experiments were made with results agreeing to within a few tenths of a milligram.

In the second set of experiments the flask was charged with 100 grams of oxalic acid and 500 c.c. strong sulphuric acid. To absorb the large quantity of CO_2 simultaneously evolved a plentiful supply of alkali was required. A wash-bottle and a long nearly horizontal tube contained strong alkaline solution, and these were followed by the tubes containing solid potash and phosphoric anhydride as before.

For the experiments of the third set *oxalic* acid was replaced by *formic*, which is more convenient as not entailing the absorption of large volumes of CO_2. In this case the charge consisted of 50 grams formate of soda, 300 c.c. strong sulphuric acid, and 150 c.c. distilled water. The water is necessary in order to prevent action in the cold, and the amount requires to be somewhat carefully adjusted. As purifiers, the long horizontal bubbler was retained and the tubes charged with solid potash and phosphoric anhydride. In this set there were four concordant experiments. The immediate results stand thus:—

Carbonic Oxide.

From ferrocyanide	2·29843
,, oxalic acid	2·29852
,, formate of soda	2·29854
Mean...	2·29850

This corresponds to the number 2·62704 for oxygen (*loc. cit.*, p. 144), and is subject to a correction (additive) of 0·00056 for the diminution of the external volume of the globe when exhausted.

The ratio of the densities of carbonic oxide and oxygen is thus 2·29906 : 2·62760; so that if the density of oxygen be taken as 32, that of carbonic oxide will be 27·9989. If, as some preliminary experiments by Dr. Scott (*Camb. Phil. Proc.*, vol. ix. p. 144, 1896) indicate, equal volumes may be taken as accurately representative of CO and of O_2, the atomic weight of carbon will be 11·9989 on the scale of oxygen = 16.

The very close agreement between the weights of carbonic oxide prepared in three different ways is some guarantee against the presence of an impurity of widely differing density. On the other hand, some careful experiments led Mr. T. W. Richards (*Amer. Acad. Proc*, vol. xviii. p. 279, 1891) to the conclusion that carbonic oxide is liable to contain considerable quantities of hydrogen or of hydrocarbons. From 5½ litres of carbonic oxide passed over hot cupric oxide he collected no less than 25 milligrams of water, and the evidence appeared to prove that the hydrogen was really derived from the carbonic oxide. Such a proportion of hydrogen would entail a deficiency in the weight of the globe of about 11 milligrams, and seems improbable in view of the good agreement of the numbers recorded. The presence of so much hydrogen in carbonic oxide is also difficult to reconcile with the well-known experiments of Prof. Dixon, who found that prolonged treatment with phosphoric anhydride was required in order to render the mixture of carbonic oxide and oxygen inexplosive. In the presence of relatively large quantities of free hydrogen (or hydrocarbons) why should traces of water vapour be so important?

In an experiment by Dr. Scott (*Chem. Soc. Trans.*, 1897, p. 564), 4 litres of carbon monoxide gave only 1·3 milligrams to the drying tube after oxidation.

I have myself made several trials of the same sort with gas prepared from formate of soda exactly as for weighing. The results were not so concordant as I had hoped,[1] but the amount of water collected was even less than that given by Dr. Scott. Indeed, I do not regard as proved the presence of hydrogen at all in the gas that I have employed.[2]

Carbonic Anhydride.

This gas was prepared from hydrochloric acid and marble, and after passing a bubbler charged with a solution of carbonate of soda, was dried by phosphoric anhydride. Previous to use, the acid was caused to boil for some time by the passage of hydrochloric acid vapour from a flask containing another charge of the acid. In a second set of experiments the marble was replaced by a solution of carbonate of soda. There is no appreciable difference between the results obtained in the two ways; and the mean, corrected for the errors of weights and for the shrinkage of the globe when exhausted, is 3·6349, corresponding to 2·6276 for oxygen. The temperature at which the globe was charged was 0° C., and the actual pressure that of the manometric gauge at about 20°, reduction being made to 15° by the use of Boyle's law. From the former paper it appears that the actual height of the mercury column at 15° is 762·511 mm.

[1] "On the Densities of Carbonic Oxide, Carbonic Anhydride, and Nitrous Oxide." By Lord Rayleigh, F.R.S. (Read at the Royal Society, December 9, 1897.)

[2] "On the Densities of the Principal Gases," *Roy. Soc. Proc.*, vol. liii, p. 134, 1893.

[1] One obstacle was the difficulty of re-oxidising the copper reduced by carbonic oxide. I have never encountered this difficulty after reduction by hydrogen.

[2] In Mr. Richards' work the gas in an imperfectly dried condition was treated with hot platinum black. Is it possible that the hydrogen was introduced at this stage?

Nitrous Oxide.

In preliminary experiments the gas was prepared in the laboratory, at as low a temperature as possible, from nitrate of ammonia, or was drawn from the iron bottles in which it is commercially supplied. The purification was by passage over potash and phosphoric anhydride. Unless special precautions are taken the gas so obtained is ten or more milligrams too light, presumably from admixture with nitrogen. In the case of the commercial supply, a better result is obtained by placing the bottles in an inverted position so as to draw from the *liquid* rather than from the *gaseous* portion.

Higher and more consistent results were arrived at from gas which had been specially treated. In consequence of the high relative solubility of nitrous oxide in water, the gas held in solution after prolonged agitation of the liquid with impure gas from any supply, will contain a much diminished proportion of nitrogen. To carry out this method on the scale required, a large (11-litre) flask was mounted on an apparatus in connection with the lathe so that it could be vigorously shaken. After the dissolved air had been sufficiently expelled by preliminary passage of N_2O, the water was cooled to near 0° C. and violently shaken for a considerable time while the gas was passing in large excess. The nitrous oxide thus purified was expelled from solution by heat, and was used to fill the globe in the usual manner.

For comparison with the results so obtained, gas purified in another manner was also examined. A small iron bottle, fully charged with the commercial material, was cooled in salt and ice and allowed somewhat suddenly to blow off half its contents. The residue drawn from the bottle in one or other position was employed for the weighings.

Nitrous Oxide (*1896*).

Aug. 15	Expelled from water	3·6359
,, 17	... ...	3·6354
,, 19	From residue after blow off, valve downwards	3·6364
,, 21	,, ,, valve upwards ...	3·6358
,, 22	,, ,, valve downwards	3·6360
	Mean	3·6359

The mean value may be taken to represent the corrected weight of the gas which fills the globe at 0° C. and at the pressure of the gauge (at 15°), corresponding to 2·6276 for oxygen.

One of the objects which I had in view in determining the density of nitrous oxide was to obtain, if it were possible, evidence as to the atomic weight of nitrogen. It may be remembered that observations upon the density of pure nitrogen, as distinguished from the atmospheric mixture containing argon which, until recently, had been confounded with pure nitrogen, led [1] to the conclusion that the densities of oxygen and nitrogen were as 16 : 14·003, thus suggesting that the atomic weight of nitrogen might really be 14 in place of 14·05, as generally received. The chemical evidence upon which the latter number rests is very indirect, and it appeared that a direct comparison of the weight of nitrous oxide and of its contained nitrogen might be of value. A suitable vessel would be filled, under known conditions, with the nitrous oxide, which would then be submitted to the action of a spiral of copper or iron wire rendered incandescent by an electric current. When all the oxygen was removed, the residual nitrogen would be measured, from which the ratio of equivalents could readily be deduced. The fact that the residual nitrogen would possess nearly the same volume as the nitrous oxide from which it was derived would present certain experimental advantages. If, indeed, the atomic weights were really as 14 : 16, the ratio (x) of volumes, after and before operations, would be given by

$$\frac{2{\cdot}2996 \times x}{3{\cdot}6359 - 2{\cdot}2996 \times x} = \frac{14}{8},$$

whence
$$x = \frac{7 \times 3{\cdot}6359}{11 \times 2{\cdot}2996} = 1{\cdot}0061,$$

3·6359 and 2·2996 being the relative weights of nitrous oxide and of nitrogen which (at 0° C. and at the pressure of the gauge) occupy the same volume. The integral numbers for the atomic weights would thus correspond to an expansion, after chemical reduction, of about one-half per cent.

But in practical operation the method lost most of its apparent simplicity. It was found that copper became unmanageable at a temperature sufficiently high for the purpose, and recourse was had to iron. Coils of iron suitably prepared and supported could be adequately heated by the current from a dynamo without twisting hopelessly out of shape; but the use of iron leads to fresh difficulties. The emission of carbonic oxide from the iron heated in vacuum continues for a very long time, and the attempt to get rid of this gas by preliminary treatment had to be abandoned. By final addition of a small quantity of oxygen (obtained by heating some permanganate of potash sealed up in one of the leading tubes) the CO could be oxidised to CO_2, and thus, along with any H_2O, be absorbed by a lump of potash placed beforehand in the working vessel. To get rid of superfluous oxygen, a coil of incandescent copper had then to be invoked, and thus the apparatus became rather complicated.

It is believed that the difficulties thus far mentioned were overcome, but nevertheless a satisfactory concordance in the final numbers was not attained. In the present position of the question no results are of value which do not discriminate with certainty between 14·05 and 14·00. The obstacle appeared to lie in a tendency of the nitrogen to pass to higher degrees of oxidation. On more than one occasion, mercury (which formed the movable boundary of an overflow chamber) was observed to be attacked. Under these circumstances I do not think it worth while to enter into further detail regarding the experiments in question.

The following summary gives the densities of the various gases relatively to air, all obtained by the same apparatus.[1] The last figure is of little significance.

Air free from H_2O and CO_2	1·00000
Oxygen	1·10535
Nitrogen and argon (atmospheric) ...	0·97209
Nitrogen	0·96737
Argon	1·37752
Carbonic oxide	0·96716
Carbonic anhydride	1·52909
Nitrous oxide	1·52951

The value obtained for hydrogen upon the same scale was 0·06960; but the researches of M. Leduc and of Prof. Morley appear to show that this number is a little too high.

THE NORTHAM PEBBLE RIDGE.

THE pebble ridge at Northam is one of the most remarkable examples of littoral drift to be found anywhere round the coast of this country.

It is thus graphically described by Charles Kingsley in "Westward Ho!":—"On this pebble ridge the surges of the bay have defeated their own fury by rolling up in the course of ages a rampart of grey boulder stones, some two miles long, as cunningly curved and smoothed and fitted as if the work had been done by human hands, which protect from the high tides of spring and autumn a fertile sheet of smooth alluvial turf. . . . It was dead calm and yet the air was full of sound—a low deep roar which hovered over downs and broad, salt marsh and river, like the roll of a thousand wheels, the tramp of endless armies, or—what it was—the thunder of a mighty surge upon the boulders of the pebble ridge. . . . The spirit of the Atlantic storm had sent forward the token of his coming in the smooth ground swell which was heard inland two miles away. To-morrow the pebbles, which were now rattling down with each retreating wave, might be leaping to the ridge top and hurled like round shot far ashore upon the marsh by the force of the advancing wave fleeing before the wrath of the western hurricane."

The particulars contained in the following description of this ridge have been obtained during a recent inspection of this part of the coast of North Devon, and from information obtained from the coastguard and others living in the locality.

The boulders which compose the ridge have been derived from the cliffs which surmount the shore of Barnstaple Bay, from Hartland Point to Westward Ho, a distance along the coast of about thirteen miles. These cliffs rise to a height of 350 feet above the level of the sea between Hartland Point and Clovelly, the height then gradually diminishing towards Westward Ho, where they terminate. They are composed principally of hard carboniferous grit of a dark slate colour, except at the western end, where this rock is interspersed with red sandstone and shale and a few pockets of glacial drift. The beach between the foot of the cliffs and low water consists of rocks cut and furrowed by the action of the sea in perpetually rolling about the large boulders which lie along its surface.

---

[1] Rayleigh and Ramsay, *Phil. Trans.*, vol. clxxxvi. p. 190, 1895.

[1] *Roy. Soc. Proc.*, vol. liii. p. 148, 1893; vol. lv. p. 340, 1894; *Phil. Trans.*, vol. clxxxvi. p. 189, 1895; *Roy. Soc. Proc.*, vol. lix. p. 201, 1896.

Beyond Westward Ho the estuary of the Taw and the Torridge commences, consisting of a vast expanse of sand bounded by sand dunes.

Large fragments of rocks have in the course of ages been dislodged from the cliffs, the remains of which perpetually rolled about by the waves of the sea during high tides, which here rise to a height of 27 feet, have acted as instruments for grinding their fellows, and battering the cliffs, and so producing the rounded boulders which now strew the beach throughout its whole length for several miles, and a portion of which, drifted along the shore of the bay, have become finally heaped up in the Northam pebble ridge.

In some parts of the cliff indents of considerable size have been cut out, and across these the boulders have collected, and been thrown up into ridges and banks. At Abbotsham, about twelve miles from Hartland, there is such a bank, the top of which is 9 feet above high water of spring tides. This ridge or bank is about 160 feet wide, the boulders of which it is composed varying in size at the top from about 12 inches in length by 4 inches in diameter to pebbles 3 inches in diameter, the largest boulders weighing about 12 lbs., those at the foot reaching to a length of 2 feet and weighing about 70 lbs. Notwithstanding the large size of the boulders of which the bank is composed its sea face is shaped into a ridge and hollow, similar to other pebble ridges, the position of which varies according to the height of previous spring tides. The pebbles left on the shelf or hollow at the spring-tide level average a smaller size than those at the other part of the bank.

The boulders scattered along the beach all lie above the level of low water of neap tides. The general direction of movement is eastwards, but the boulders follow the line of the coast and the set of the flood tide. This direction varies round the bay from eastward to south-east, east again and then north-east, and finally south-east. The direction of the wind which drives the heaviest sea into the bay is from the north-west.

The Northam pebble ridge commences at the termination of the cliffs, and runs in a north north-easterly direction for upwards of two miles across a low flat plain which is below the level of high tides, until it falls into some hummocks of blown sand. It thus forms a natural embankment enclosing a tract of 900 acres of sandy and alluvial grass land which is used for grazing purposes, and also as golf links. After running along the foot of the sand hills for a short distance the pebble bank turns sharply to the south-east up the course of the outfall of the two rivers, the boulders diminishing in size to pebbles and coarse sand. There is an outlying bed of boulders, known as the Pulley, situated some distance from the bank, on the edge of the low-water channel of the river, but these appear to be a fixed deposit which neither increases nor diminishes in size.

The ridge is approximately 180 feet wide at the base and 20 feet high, the top being about 25 to 30 feet wide and 6 feet above high water of spring tides. The boulders on the top of the bank vary in size from about 12 inches in length by 6 inches in diameter to pebbles an inch in diameter, the average size being about 8 inches in length by 4 inches in diameter, the largest being about 12 inches long and weighing from 40 to 50 lbs. At the foot of the bank are to be found boulders measuring from 15 to 18 inches in length and weighing from 100 to 150 lbs. The size of the boulders does not vary much throughout the length of the bank. The greatest collection of small stones appears to be on the shelf or hollow at the level of spring tides, where the pebbles vary from about half an inch to four inches in diameter. Some of the larger boulders have been drifted quite to the far end of the bank.

The boulders consist entirely of the same description of slate-coloured carboniferous grit as the cliffs from Hartland to Abbotsham are composed of, and there can be no doubt that they have drifted from this part of the coast. At the commencement of the ridge there are fairly numerous samples of shale and red sandstone pebbles from the cliffs between Westward Ho and Abbotsham, but these gradually disappear further along the ridge, the softer rock of which they are composed evidently not being able to withstand the constant grinding process produced by the wave action of the tides and wind. From the foot of the bank to low water the beach is covered with sand, which dries from a third of a mile at the south end to three-quarters of a mile at the northern end.

There is a very slow but continuous drift or movement of the boulders along the bank northwards. The progress of the ridge being stopped by the sand hills, the bank has bifurcated at this point, a new or double bank now forming, a circumstance which has occurred within the knowledge of those who have known the bank all their lives.

The boulders composing the ridge are in perpetual motion during the time that the bank is covered by the sea at spring tides. Even in calm weather in summer the whole face of the bank is continually changing under the influence of the wave action of the flood and ebb tide, which is of sufficient force to cause the movement of even large boulders. Observers who have carefully watched this movement and marked individual stones find that they are never in the same place two tides running, and each spring tide leaves its impress in a hollow and ridge at high-water mark.

In heavy on-shore gales these ridges and hollows are obliterated, and the face of the bank is pulled down seaward, the extent to which this is carried depending on the force and duration of the gale. After the storm, and when the height and force of the waves have subsided, the pebbles begin to move back again; the contour of the bank becomes more steep, and is soon restored to its normal condition.

During the winter at the end of 1896 there was a succession of westerly gales, culminating in a very heavy gale from the north-west. The bank was torn down and so lowered that the waves broke over it and inundated the enclosed land. Some of the largest boulders were thrown over the top of the ridge and hurled a considerable distance inland, where they now remain as a witness to the force of the gale. The disturbance of the boulders was so great under the action of the waves, that after the gale it was found that the base of the bank was moved ten yards inland, the clay bed on which it had rested previously being exposed. A somewhat similar movement took place during a gale about twenty years previously.

The peculiarity of this pebble ridge, and the way in which it differs from ordinary shingle banks, is in the large size of the boulders drifted along the coast, and heaped up by the action of the waves and tides. W. H. WHEELER.

RANDOM SELECTION.

THIS memoir[1] is the first of a series dealing with the problem of selection, namely the measurement of the changes in the characters of a race, when selection has acted upon any one, two, or more of them. The problem mathematically differs considerably according to the nature of the selection. But in all cases the general result is the same, the selection of any organ, whether by size, variability, or correlation with other organs, changes the sizes, variabilities, correlations of all other organs, whether directly correlated with the first organ, or only indirectly correlated with it owing to correlation with other organs which are correlated with the first organ. (A and C may have no correlation with each other, but both be correlated with B, *e.g.* two parents in the absence of sexual selection and their offspring.) The chief types of selection which have to be treated independently are:—

(i.) *Random Selection* or *Sample Selection*.—The isolation of a group out of a larger population. This will generally have characters divergent from those of the general population, but which form in themselves a correlated system of divergences.

(ii.) *Epidemic Selection*.—Selection which takes place so quickly that the growth or reproduction of the population may be neglected. For example, a severe winter or a pestilence.

(iii.) *Auxetic Selection*, or long-continued selection which allows during its action for growth, but not for reproduction. For example, diseases of childhood.

(iv.) *Gonimic Selection*, or long-continued selection which allows during its action for reproduction. For example, physical and mental qualities, pressure of other populations. These forms of selection require very different mathematical treatment; it is not at all clear, that they have always been sufficiently distinguished by writers on the theory of evolution. The above paper covers only the ground of the first kind of selection, random selection, but the memoir on epidemic selection is already completed, and the theory of the other cases advanced. The importance of random selection not only arises from the differentiation of species by isolation of small groups from a general population, but also from the fact that every measurement on a population is really a measurement on a more or less extensive random selection or sample. Hence the theory of random selection is also the theory of the probable errors of the frequency constants for any race. It enables us to determine the accuracy with which we have measured the chief racial constants.

---

[1] Contributions to the Mathematical Theory of Evolution. IV. On the Probable Errors of Frequency Constants, and on the Influence of Random Selection on Variation and Correlation, by Karl Pearson and L. N. G. Filon. (Royal Society, Nov. 25, 1897.)

Let the frequency-surface giving the distribution of a population with regard to n-organs be

$$z = f(x_1\, x_2,\, x_3 \dots x_n,\, c_1,\, c_2\, c_3 \dots c_q)$$

where $c_1\, c_2 \dots c_q$ are the q constants which determine the characters of the population. Then the surfaces for the distribution of the errors in $c_1,\, c_2 \dots c_q$ is given approximately by

$$z = z_0 e^{-\frac{1}{2}(a_{11}\, c_1^2 + 2a_{12}c_1c_2 + \dots)}$$

where

$$a_{tu} = -\iiint \dots z \frac{d^2 \log z}{dc_t dc_u} dx_1 dx_2 \dots dx_n$$

Higher terms can be evaluated if needful; we have then a skew correlation of the system of errors. Approximately the divergences of any random selection from the characters of the general population form in themselves a normally correlated system, and we can predict from a knowledge of the divergence in one character the probable divergences in all the others.

The general formulæ are applied to the problems of

(i.) *The random selection out of a population having* n *normally correlated organs.*

If one character be changed, say the variability of one organ be altered, it is shown how the probable changes in all the other characters may be found; for example, the changes in the correlation of other organs. This is the death-blow to any theory that either variability or correlation can be constant for local races.

(ii.) *Skew Variation*, for all the three types discussed in a previous memoir.

Criteria are obtained for determining when skewness is significant; when the mode really diverges from the mean, &c.

In many cases in which the normal curve of errors is used, the skewness is really significant, and thus many of the results used are illegitimate. For example, personal equation is generally sensibly skew, curves for size of organs during growth, and nearly all cases of botanical distribution.

These points are illustrated in the memoir by three numerical examples:—

(I.) Müllerian glands in the legs of swine; data from the observations of two American naturalists. The skewness can be determined with less than 5 per cent. of probable error. It is therefore significant, and the use by the above-mentioned biologists of the ordinary theory of errors is in this case to be deprecated.

(II.) Enteric fever. Skewness is known to 1 per cent. of probable error.

The effect of raising mean age, or altering the incidence, &c. on the character of the disease follows at once from the tables given.

(III.) Stature during growth; a critical case, taken because the distribution is almost normal. The skewness is, however, probably significant, and the influence indicated of random selection on stature during growth is in accordance with experience.

MODIFICATION OF THE GREAT LAKES BY EARTH MOVEMENT.[1]

THE history of the Great Lakes practically begins with the melting of the Pleistocene ice-sheet. They may have existed before the invasion of the ice, but if so their drainage system is unknown. The ice came from the north and north-east, and, spreading over the whole Laurentian basin, invaded the drainage districts of the Mississippi, Ohio, Susquehanna and Hudson. During its wandering there was a long period when the waters were ponded between the ice front and the uplands south of the Laurentian basin, forming a series of glacial lakes whose outlets were southward through various low passes. A great stream from the Erie basin crossed the divide at Fort Wayne to the Wabash river. A river of the magnitude of the Niagara afterwards flowed from the Michigan basin across the divide at Chicago to the Illinois river; and still later the chief outlet was from the Ontario basin across the divide at Rome to the Mohawk valley.

The positions of the glacial lakes are also marked by shore-lines, consisting of terraces, cliffs, and ridges, the strands and spits formed by their waves. Several of these shore-lines have been traced for hundreds of miles, and wherever they are thoroughly studied it is found that they no longer lie level, but have gentle slopes towards the south and south-west. Formed at the edges of water surfaces, they must originally have been level, and their present lack of horizontality is due to unequal uplift of the land. The region has been tilted towards the south-south-west. The different shore-lines are not strictly parallel, and their gradients vary from place to place, ranging from a few inches to three or four feet to the mile.

Early History of the Lakes.

The epoch of glacial lakes, or lakes partly bounded by ice, ended with the disappearance of the ice-field, and there remained only lakes of the modern type, wholly surrounded by land. These were formed one at a time, and the first to appear was in the Erie basin. It was much smaller than the modern lake, because the basin was then comparatively low at the north-east. Instead of reaching from the site of Buffalo to the site of Toledo, it extended only to a point opposite the present city of Erie, and it was but one-sixth as large as the modern lake. Since that time the land has gradually risen at the north, canting the basin towards the south, and the lake has gradually encroached upon the lowlands of its valley.

The next great lake to be released from the domination of the ice was probably Ontario, though the order of precedence is here not equally clear. Before the Ontario valley held a land-bound lake it was occupied by a gulf of the ocean. Owing to the different attitude of the land, the water surface of this gulf was not parallel to the present lake surface, but inclined at an angle. In the extreme north-east, in the vicinity of the Thousand Islands, the marine shores are nearly 200 feet above the present water level, but they descend southward and westward, passing beneath the lake level near Oswego, and towards the western end of the lake must be submerged several hundred feet. This condition was of short duration, and the rising land soon divided the waters, establishing Lake Ontario as an independent water body. The same peculiarity of land attitude which made the original Erie a small lake served to limit the extent of Ontario, but the restriction was less in amount because of the steeper slopes of the Ontario basin. Here again the southward tilting of the land had the effect of lifting the point of outlet and enlarging the expanse of the lake.

There is some reason to think that the upper lakes, Huron, Michigan and Superior, were at first open to the sea, so as to constitute a gulf, but the evidence is not so full as could be desired. When the normal lacustrine condition was established they were at first a single lake instead of three, and the outlet, instead of being southward from Lake Huron, was north-eastward from Georgian bay, the outlet river following the valleys of the Mattawa and Ottawa to the St. Lawrence. The triple lake is known to us chiefly through the labours of Mr. F. B. Taylor, who has made extensive studies of its shore-line. This line, called the Nipissing shore-line, is not wholly submerged, like the old shores of lakes Erie and Ontario, but lies chiefly above the present water surfaces. It has been recognised at many points about Lake Superior and the northern parts of lakes Huron and Michigan, and measurements of its height show that its plane has a remarkably uniform dip, at 7 inches per mile, in a south-south-west direction, or, more exactly, S. 27° W. The southward tilting of the land, involving the uplift of the point of outlet, increased the capacity of the basin and the volume of the lake, gradually carrying the coast-line southward in Lake Huron and Lake Michigan until finally it reached the low pass at Port Huron, and the water overflowed *viâ* the St. Clair and Detroit channels to Lake Erie. The outlet by way of the Ottawa was then abandoned, and a continuance of the uplift caused the water to slowly recede from its northern shores. This change after a time separated Lake Superior from the other lakes, bringing the St. Marys river into existence, and eventually the present condition was reached.

---

[1] Abridged from a paper, by Prof. G. K. Gilbert, in the *National Geographic Magazine* (September 1897).

These various changes are so intimately related to the history of the Niagara river that the Niagara time estimates, based on the erosion of the gorge by the cataract, can be applied to them. Lake Erie has existed approximately as long as the Niagara river, and its age should probably be reckoned in tens of thousands or hundreds of thousands of years. Lake Ontario is much younger. All that can be said of the beginning of Great Lake Nipissing is that it came long after the beginning of Lake Erie, but the date of its ending, through the transfer of outlet from the Mattawa to the St. Clair, is more definitely known. That event is estimated by Taylor to have occurred between 5000 and 10,000 years ago.

The lake history thus briefly sketched is characterised by a progressive change in the attitude of the land, the northern and north-eastern portions of the region becoming higher, so as to turn the waters more and more towards the south-west. The latest change, from Great Lake Nipissing to Great Lakes Superior, Michigan and Huron, involving an uplift at the north of more than 100 feet, has taken place within so short a period that we are naturally led to inquire whether it has yet ceased. Is it not probable that the land is still rising at the north, and the lakes are still encroaching on their southern shores? Dr. J. W. Spencer, who has been an active explorer of the shore-lines of the glacial lakes, and has given much study to related problems, is of opinion that the movements are not complete, and predicts that they will result in the restoration of the Chicago outlet of Lake Michigan and the drying of Niagara.

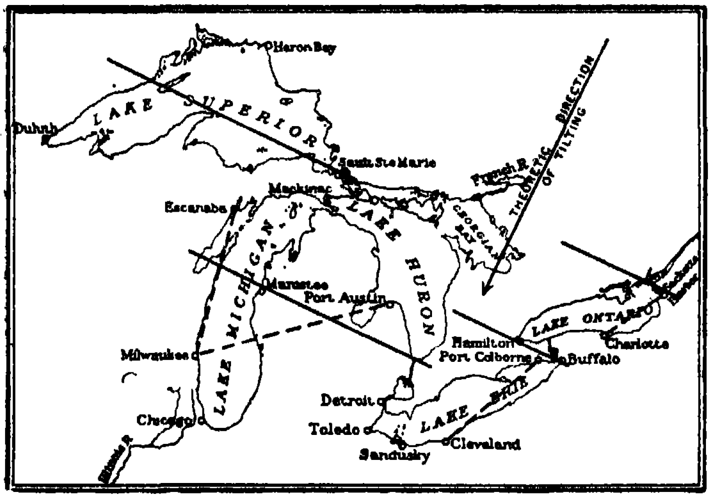

FIG. 1.—Map of the Great Lakes, showing pairs of gauging stations and isobases of outlets. The isobases are marked by full lines. Broken lines show the pairs of stations.

Measurements of Changes in the Shore-lines.

The importance of testing this question by actual measurements was impressed upon me several years ago, and I endeavoured to secure the institution of an elaborate set of observations to that end. Failing in this, I undertook a less expensive investigation, which began with the examination of existing records of lake height as recorded by gauge readings, and was continued by the establishment of a number of gauge stations in 1896.

If the volume of a lake were invariable, and if its water were in perfect equilibrium under gravity, its surface would be constant and level, and any variation due to changes in the height of the land could be directly determined by observations on the position of the water surface with reference to the land; but these conditions are never realised in the case of the Great Lakes, where the volume continually changes and the water is always in motion. The investigator therefore has to arrange his measurements so as to eliminate the effect of such changes.

The various oscillations of the water, though differing widely in amplitude, rate and cause, yet coexist, and they make the actual movement of the water surface highly complex. The complexity of movement seriously interferes with the use of the water plane as a datum level for the measurement of earth movements, and a system of observations for that purpose needs to be planned with much care. The main principles of such a system are, however, simple, and may readily be stated. The most important is that the direct measurement of the heights of individual points should not be attempted, but comparison should always be made between two points, their relative height being measured by means of the water surface used as a levelling instrument.

It will not be necessary to give here the details of observation and computation, as they are fully set forth in a paper soon to be printed by the U.S. Geological Survey, but the general scope of the work may be briefly outlined. As the tilting shown by the geological data was towards the south-south-west, stations were, so far as possible, selected to test the question of motion in that direction. The most easterly pair were Sacketts Harbour and Charlotte, New York, connected by the water surface of Lake Ontario (Fig. 1). From observations by the U.S. Lake Survey in 1874, it appeared that a bench mark on the old lighthouse in Charlotte was then 18·531 feet above a certain point on the Masonic Temple in Sacketts Harbour. In 1896 the measurement was repeated, and the difference found to be 18·470 feet, the point at Sacketts Harbour having gone up, as compared to the point at Charlotte, 0·061 foot, or about three-fourths of an inch. Similarly it was found that between 1858 and 1895 a point in Port Colborne, at the head of the Welland Canal, as compared to a point in Cleveland, Ohio, rose 0·239 foot, or nearly three inches. Between 1876 and 1896 a point at Port Austin, Michigan, on the shore of Lake Huron, as compared to a point in Milwaukee, on the shore of Lake Michigan, rose 0·137 foot, or one and one-half inches; and in the same period a point in Escanaba, at the north end of Lake Michigan, as compared to the same point in Milwaukee, rose 0·161 foot, or about two inches.

There is not one of these determinations that is free from doubt; buildings and other structures on which the benches were marked may have settled; mistakes may have been made in the earlier levelling, when there was no thought of subjecting the results to so delicate a test; and there are various other possible sources of error to which no checks can be applied. But the fact that all the measurements indicate tilting in the direction predicted by theory, inspires confidence in their verdict.

The stations of the several pairs are at different distances apart, the directions of the lines connecting them make various angles with the theoretical direction of tilting, and the time intervals separating the measurements are different. To reduce the results to common terms, I have computed from each the rate of tilting it implies in the theoretical direction, S. 27° W., and determined the change in relative height of the ends of a line 100 miles long during a century.

Compared in this way, the results are remarkably harmonious, the computed rates of tilting ranging only from 0·37 foot to 0·46 foot per 100 miles per century; and in view of this harmony it is not easy to avoid the conviction that the buildings are firm and stable, that the engineers ran their level lines with accuracy, that all the various possible accidents were escaped, and that we have here a veritable record of the slow tilting of the broad lake-bearing plain.

The computed mean rate of tilting, 0·42 foot per 100 miles per century, is not entitled to the same confidence as the fact of tilting. Its probable error, the mathematical measure of precision derived from the discordance of the observational data, is rather large, being one-ninth of the whole quantity measured. Perhaps it would be safe to say that the general rate of tilting, which may or may not be uniform for the whole region, falls between 0·30 and 0·55 foot.

Future of the Great Lakes.

The geographical effects of the tilting are of scientific and economic importance. Evidently the height of lake water at a lake's outlet is regulated by the discharge, and is not affected by slow changes in the attitude of the basin; but at other points of the shore the water advances or retreats as the basin is tipped. Consider, for example, Lake Superior. On the map (Fig. 1) a line has been drawn through the outlet at the head of St. Marys River in a direction at right angles to the direction of tilting. All points on this line, called the *isobase* of the outlet, are raised or lowered equally by the tilting, and are unchanged with reference to one another. All points south-west of it are lowered, the amount varying with their distances from the line, and all points to the north-east are raised. The water, always holding its surface level, and always regulated in volume by the discharge at the outlet, retreats from the rising north-east coasts, and encroaches on the sinking south-west coasts. Assuming the rate of tilting to be 0·42 foot per 100 miles per century, the mean lake level is rising at Duluth 6 inches per century and falling at Heron Bay 5 inches. Where the isobase intersects the north-western shore, which happens to be at the international boundary, there is no change.

Lake Ontario lies altogether south-west of the isobase of its outlet, and the water is encroaching on all its shores. The estimated vertical rise at Hamilton is 6 inches per century. The whole coast of Lake Erie also is being submerged, the estimated rate at Toledo and Sandusky being 8 or 9 inches per century.

The isobase of the double Lake Huron-Michigan passes south-west of Lake Huron and crosses Lake Michigan. All coasts of Lake Huron are therefore rising as compared to the outlet, and the consequent apparent lowering of the mean water surface is estimated at 6 inches per century for Mackinac, and at 10 inches for the mouth of the French river on Georgian Bay. In Lake Michigan the line of no change passes near Manistee, Michigan. At Escanaba the estimated fall of the water is 4 inches per century; at Milwaukee the estimated rise is 5 or 6 inches, and at Chicago between 9 and 10 inches.

These slow changes of mean water level are concealed from ordinary observation by the more rapid and impressive changes due to variations of volume, but they are worthy of consideration in the planning of engineering works of a permanent character, and there is at least one place where their influence is of moment to a large community. The city of Chicago is built on a smooth plain little above the high-water level of Lake Michigan. Every decade the mean level of the water is an inch higher, and the margin of safety is so narrow that inches are valuable. Already the older part of the city has lifted itself several feet to secure better drainage, and the time will surely come when other measures of protection are imperatively demanded.

Looking to the more distant future, we may estimate the date at which the geographical revolution, prophesied by Spencer, will occur. Near Chicago, as already mentioned, is an old channel made by the outlet of a glacial lake. The bed of the channel at the summit of the pass is about 8 feet above the mean level of Lake Michigan and 5 feet above the highest level. In 500 or 600 years (assuming the estimated rate of tilting) high stages of the lake will reach the pass, and the artificial discharge by canal will be supplemented by an intermittent natural discharge. In 1000 years the discharge will occur at ordinary lake stages, and after 1500 years it will be continuous. In about 2000 years the discharge from Lake Michigan-Huron-Erie, which will then have substantially the same level, will be equally divided between the western outlet at Chicago and the eastern at Buffalo. In 2500 years the Niagara river will have become an intermittent stream, and in 3000 years all its water will have been diverted to the Chicago outlet, the Illinois river, the Mississippi river, and the Gulf of Mexico.

FORESTS AND RAINFALL.[1]

CAN it be possible that the cutting away of forests affects the amount of precipitation in any locality? To many, no doubt, this question will seem easy of answer; but we find the results of study by no means reassuring, and recent investigations have led to almost diametrically opposite conclusions, depending, somewhat at least, upon the feeling of the writer. When we reflect that our rain storms are of very wide extent, oftentimes over 1000 miles in diameter, and may take their origin and bring their moisture from distances of 1000 miles or more, the thought that man, by his puny efforts, may change their action, or modify it in any manner, seems ridiculous in the extreme.

It has been well established that forests have a most important bearing upon the conservation of rainfall; that the forest floor permits a seepage of water to the source of springs, and thus maintains their steady flow; that they hold back the precipitation that falls, especially in the form of snow, thus preventing or ameliorating the effects of dangerous freshets. There is not the slightest doubt of their great importance to the welfare of man, but all these facts do not affect the question of their influence upon precipitation. The following paper is prepared from the standpoint of a meteorologist, and is an attempt to present facts.

The Historical Argument.

Formerly the historical argument was a favourite one. I quote one of these: "It is a familiar fact that there are many regions in Asia and southern Europe, once exceedingly fertile and densely populated, that are now utterly sterile and desolate. The country bordering on the Euphrates and portions of Turkey, Greece, Egypt, Italy and Spain are now incapable of cultivation from lack of rain due to deforestation." The most fertile of all provinces in Bucharia was that of Sogd. Malte Brun said, in 1826, "For eight days we may travel and not be out of one delicious garden" In 1876 another writer says of this same region: "Within thirty years this was one of the most fertile spots of central Asia, a country which, when well wooded and watered, was a terrestrial paradise. But within the last twenty-five years a mania of clearing has seized upon the people, and all the great forests have been cut away, and the little that remained was ravaged by fire during a civil war. The consequences followed quickly, and this country has been transformed into a kind of arid desert. The water-courses are dried up and the irrigating canals are empty." It has also been said that in the older settled portions of New England and the Middle States there are arid hills and worn-out fields, due to the falling off of precipitation from the cutting away of the forest growth. Such quotations and statements might be made to fill a large volume. Without more precise data as to rainfall it would be hazardous to conclude that we have here a case of cause and effect. It is certain that the fertility of these regions in ancient times was due to stupendous irrigating devices and canals, and when these were neglected, through wars and other untoward circumstances, the fertility necessarily ceased. It is certain that there are ruins of enormous irrigating ditches and canals in Babylonia, where history indicates that there was once a teeming population and great fertility, but where now only a sandy desert greets the eye.

Constancy of Rainfall.

It has been said that where our densest forests are found there we have the greatest precipitation. There is no way whereby we can see that such forests would have started unless favoured by rainfall, so that the presence of the forest rather indicated the earlier occurrence of practically the same rainfall as at present. Meteorologists are agreed that there has been practically no change in the climate of the world since the earliest mention of such climates. Plants found in mummy cases in Egypt that were plucked thousands of years ago show the same size as those now found in that land. The "early and the latter rains" are experienced in Palestine to-day just as they were four thousand years ago. Jordan "overflows all its banks" to-day, in February, precisely as it did in Joshua's day. When we come down to recent times and to the records of rainfall measured in New England for more than one hundred years, or, at least, before and since the forests were cut, we find a constancy in the rainfall which shows its entire independence of man's efforts. Here it should be noted that totally barren lands of any extent, in New England for example, are to be found only in imagination. Even where the forest has been cut away mercilessly there springs up a growth of sprouts which covers the ground, and answers almost the same purpose in causing rainfall (if there is any effect of that kind) as the forest. Even where land is entirely cleared of a forest we have at times the green pasture, and at others still heavier crops which leave the ground anything but a sandy waste.

Rainfall Measurements in Forests and Open Fields.

But the strongest argument adduced in the past to show the influence of forest on rainfall has existed in a comparison between rain-gauge measures in the forest and the open field

---

[1] A paper by Prof. H. A. Hazen, presented at the annual meeting of the American Forestry Association at Nashville, Tenn., September 22. (Abridged from the *Monthly Weather Review*.)

Such records have been made for more than thirty years in France and Germany, and surely we must have here, if anywhere, a sufficient proof of a forest's influence.

Admitting that we have perfect instruments and careful observers, there still remains a most serious doubt as to the immediate environment of each gauge and as to the possibility of a direct comparison. It is probable that no two gauges 2000 feet apart can be placed so as to catch the same amount of rain, though to all appearances the exposure is faultless in each case.

Extreme caution is therefore needed in arriving at conclusions from comparisons between gauges in forests and in the open. One of the best of all researches in this line has been conducted at Nancy, in France. Within a distance of five or six miles there have been four stations established. At Nancy in the open, and at Belle-Fontaine in the forest; and, 500 feet higher vertically, Amance (open) and Cinq-Tranchées (forest). At Nancy and Belle-Fontaine the observations extend over twenty-five years. A comparison of the records in groups of eight, eight, and nine years was made, with the result that while the first eight years showed a very slight excess in the forest rainfall over that in the open field, in the last nine years (including 1894, last published) the open station showed a little more rain than the forest station. These observations were made with particular care, for the purpose of exactly determining the influence, and may be relied on if the environments of the gauges were comparable. At Amance (open) and Cinq-Tranchées (forest) the observations have not been quite so regular, though there are twenty-five full years of records at these two stations, but not the same years as at the other stations. The comparison in this case makes the rainfall more than 20 per cent. greater in the forest than in the open. It should be borne in mind, however, that these two stations are on an eminence, and are not strictly comparable, and this result cannot vitiate that at the two other stations, which shows no effect.

In Germany we have a rather remarkable record of a slightly different character. Lintzel is a station on the Luneburg Heath, which began to be planted with trees in 1887, at the rate of 1000 to 1500 acres a year, and in a few years over 8000 acres were covered. In the midst of this forest is the meteorologic station in an open field of some seventy-five acres. Before planting the forest, 97 per cent. of the surface was field, meadow, or heath, and afterwards 80 per cent. was forest and 20 per cent. was roads, open field, and heath. Around this station, pretty evenly distributed, and within fifty miles, there are thirteen rainfall stations which have been carefully established, and presumably are comparable with the Lintzel station in the midst of the growing forest. There are no means of knowing whether any of these stations have been changed or not, but for our purpose we may consider the material homogeneous, and treat it accordingly. Records from 1882 to 1896 (fifteen years) are available. Charts were prepared for each year showing the ratio between the Lintzel record and that at each station of the thirteen. The results do not show that the afforestation has had any appreciable effect upon the precipitation; in 1884 the ratio was 101, while in 1893, nine years later, it was 96. It is probable, however, that no definite and unassailable result can ever be obtained either by the method adopted in France or this later one in Germany. The rainfall is so variable within a distance of even a mile or two; and it is so difficult, if not impossible, to obtain similar environments at all the stations, that no decisive result can be obtained. It will be readily seen that the multiplication of stations will do no good, and, above all, that the observation of rainfall under trees in a forest is absolutely useless for any such discussion or study as this.

Need of Further Evidence.

It seems probable that if two or three lines of stations could be established a mile or two apart on four sides of an enormous forest, each line to have a dozen stations or so, about 3000 feet apart, four of the stations to be outside of the forest, and the others each in a large cleared space of at least two acres extent in the forest, something decisive might be obtained. It should be noted, however, that from the evidence already accumulated there would be very little to be gained by a further study of the question. It is certain that the effect, if there be one, is almost inappreciable. The favouring conditions over the forest are balanced by those not favouring, and the integrated effect is practically the same in the two cases.

Prof. H. F. Blanford determined from a most careful series of records, from which all known errors had been eliminated, that the forest had a tendency to give 2 per cent. more rain than contiguous open fields. That is, if an open place had 50 inches of rain in a year, a near-by forest would have only 51 inches, which is practically inappreciable.

It would be an interesting study to select all those cases in experiments in forest and near-by fields in which the wind was blowing either from the forest to the field, or *vice versâ*. It is evident that if there is any effect on rainfall by the forest, it would be vitiated, if not exactly reversed by such winds.

There is a class of visual observations which seem to show an effect upon rainfall by the forest. Probably many have seen heavy clouds passing over a plain, but which only precipitated as they passed over a forest. Also in a hilly region it is a frequent phenomenon that fog and low-lying cloud hover near a forest, and not over an open plain. One also notes very often, in passing into a forest on a damp day, that the trees drip moisture, possibly condensed from moisture evaporated from the damp earth underneath. Observations of this nature, however, cannot ordinarily be checked by instrumental means, but show in a general way that the forest tends to conserve vapour and moisture which in the case of the open field would be diffused into the atmosphere.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DR. G. H. RENDALL, the Principal of University College, Liverpool, has been appointed Head-Master of Charterhouse School.

SIR JOHN GORST, in the course of an address at Bristol on Thursday last, is reported by the *Times* to have said that the promotion of technical education was confronted by two obstacles—the backward condition of elementary education and the want of organisation in the provision of secondary education. A good sound system of elementary education must be the groundwork for higher education, and he urged reform of the system which at present relieved children from compulsory attendance when inadequately equipped. The improvement of the organisation of secondary schools was really a matter for the people themselves. There was nothing to prevent technical instruction committees from becoming thoroughly representative and effective organisations.

THE most satisfactory point to us in the Report just issued by the Oxford University Extension Delegacy refers to the Extension College at Reading. The college is doing excellent work, more particularly in agriculture, and has amply justified its existence. New buildings are, however, imperatively needed, and in response to an appeal for 12,000*l*., 9,000*l*. has already been promised, and the new wing has been begun. The building scheme, planned four years ago, will be completed by next summer, and H.R.H. the Prince of Wales has promised to perform the opening ceremony. The educational work of the college has been attended with great success during the past year. With regard to the courses of lectures delivered under the auspices of the Delegacy during the year 1896-97, we notice that out of a total of 146 courses, only nineteen were on scientific subjects.

IN the course of a presidential address recently delivered before the Kansas Academy of Sciences, Prof. S. W. Williston severely criticised the system of education which makes language studies compulsory, and all, or nearly all, the sciences optional. Many educationists will find themselves in agreement with the following opinions expressed by Prof. Williston:—"I claim broadly and emphatically that the natural sciences, any or all of them, are as valuable and as necessary as pure cultural studies as are the languages; that intelligent and successful study of them will do as much, if not more, in making the student a broad man, a successful man, as will the study of Latin or Greek. And they will do more in making him an honest man. Nowhere in all the broad field of knowledge will he learn better to think exactly than in the natural sciences. Nowhere will he be more impressed with the importance of truth for truth's sake. . . . Were I, then, to say what the universities and colleges ought to do, it would be this: make all the ancient language requirements for admission optional, and demand as much preparation in the physical and biological sciences as in the foreign languages. The preparation in English should be made far more rigorous.

and thorough. In the college course, if anything besides English is required, and I think there should be, I would have the natural science as necessary a part of the education as language and mathematics. I would not have it possible for a student to graduate from the college without having studied, and thoroughly studied, mathematics as far as trigonometry, at least one foreign language, and at least one physical and one biological science. And I do not mean a few weeks of study in any of these branches, but exhaustive, careful, critical study. The methods of study in all these branches are diverse, and are absolutely essential for symmetrical mind-building."

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 25.—"Further Note on the Transplantation and Growth of Mammalian Ova within a Uterine Foster-Mother." By Walter Heape, M.A., Trinity College, Cambridge.

In 1890 an experiment was recorded (*Roy. Soc. Proc.*, vol. xlviii.), designed to show that it is possible to make use of the uterus of one variety of rabbit as a medium for the growth and complete fœtal development of fertilised ova of another variety of rabbit. The experiment was further undertaken in order to determine what effect, if any, a uterine foster-mother would have upon her foster-children, and whether or not the presence, during development, of foreign ova in the uterus of a mother would affect offspring of that mother present in the uterus at the same time. In this experiment, two fertilised ova obtained from an Angora doe rabbit which had been inseminated thirty-two hours previously by an Angora buck, were inserted into the fallopian tube of a Belgian Hare doe, which had been inseminated three hours before by a buck of the same breed as herself; and in due course the Belgian Hare doe littered six young, four of which were Belgian Hares, while the other two were Angoras. This year experiments were made with Dutch and Belgian Hare rabbits, and the method adopted was the same as that described above, the result being that the Belgian Hare foster-mother gave birth to seven young, of which five were Belgian Hares and two were apparently Dutch. Both these Dutch young were, however, irregularly marked, and it appeared possible, after all, either (1) that the Belgian Hare foster-mother had influenced the Dutch fertilised ova, or (2) that these two young were really a cross between Dutch and Belgian Hare.

In order to test the first of these possibilities, the same Dutch buck was put to a tried, thoroughbred Dutch doe, and she produced a litter, every one of which was badly marked, thus showing that the bad marking of the foster-children can be justly attributed to their father's influence. The second possibility was more difficult to test. A cross between the Dutch buck and the Belgian Hare foster-mother was obviously possible, for when the foreign Dutch segmenting ova were introduced into the fallopian tube of the Belgian Hare foster-mother, they were still surrounded by spermatozoa from the Dutch buck, which were still alive, though failing in vigour. But the Belgian Hare doe had been inseminated by a Belgian Hare buck just before the operation, and the spermatozoa from this buck would arrive at the end of the fallopian tube before ovulation took place; it would be at least twenty-four hours younger than the foreign Dutch spermatozoa, and both more vigorous and in far greater numbers than the latter. The possibilities are distinctly in favour of the host of younger and more vigorous Belgian Hare spermatozoa beating the few older and less vigorous, foreign, Dutch spermatozoa in the struggle for the Belgian Hare ova; but, at the same time, it is possible that the latter won. The only way to test this at all seemed to be by crossing the same Dutch buck with Belgian Hare does, and comparing the offspring of such crosses with the young foster children. This was done, and two Belgian Hare does each produced, in consequence, five young. Of these, three were Belgian hares splashed with white, one was black and white, three were fawn or fawn and white (the fawn being mixed with a delicate bluish dun shade), and three were thoroughbred Belgian Hares. The father's influence was seen in the introduction of white and in the fawn and dun colours. None of the young, however, at all closely resembled the Dutch breed.

With regard to the foster-children, one of them died at an early age, but the second lived, and is now more typically Dutch than it was when younger; it is coloured and shaped remarkably like the Dutch doe from which the foreign fertilised ova were obtained. The remarkable likeness is in itself very strong evidence of the origin of this young one, and when considered in conjunction with the results obtained by crossing the Dutch buck with Belgian Hare does, there can be little doubt it was derived from Dutch parents. This result, supported by the result obtained in 1890, is greatly in favour of the contention, that it is possible to make use of a uterine foster-mother, and to do so without thereby influencing any of the young which are nourished by her.

It is worthy of notice, if the above is true, that in case telegony be actually demonstrated, the characteristics of a primary husband transmitted to the offspring got by a secondary husband, can only be so transmitted through the ova of the mother.

"Mathematical Contributions to the Theory of Evolution. IV. On the probable Errors of Frequency Constants and on the Influence of Random Selection on Variation and Correlation." By Karl Pearson, F.R.S., and L. N. G. Filon, University College, London.

A brief indication of the nature of the contents of this paper is given on p. 210.

December 9.—"On the Calculation of the Coefficient of Mutual Induction of a Circle and a Coaxial Helix, and of the Electromagnetic Force between a Helical Current and a Uniform Coaxial Circular Cylindrical Current Sheet." By J. Viriamu Jones, F.R.S.

Zoological Society, December 14.—Lieut.-Colonel H. H. Godwin-Austen, F.R.S., Vice-President, in the chair.—Mr. G. A. Boulenger, F.R.S., offered some further remarks upon the Siluroid Fish, *Vandellia cirrhosa*.—A communication was read from Dr. E. A. Goeldi, "On *Lepidosiren paradoxa* from the Amazons." This memoir treated of the geographical distribution of the *Lepidosiren* on the Amazons, and of its external structure and dimensions, and gave an account of its habits in a natural and captive state.—Mr. J. Graham Kerr gave an account of his recent expedition, along with Mr. Budgett, to the Chaco of Paraguay in quest of *Lepidosiren*: and made remarks on its habits as there observed. Mr. Kerr also gave a general account of the early stages of its development, drawing special attention to the presence in the larva of external gills and a sucker similar to those of the Amphibia.—A communication was read from Dr. A. G. Butler, containing a list of thirty-three species of butterflies obtained by Mr. F. Gillett in Somaliland during the present year, and giving the dates of the capture of the specimens and their localities.—Mr. Oldfield Thomas read a paper entitled "On the Mammals obtained by Mr. A. Whyte in North Nyasaland, and presented to the British Museum by Sir H. H. Johnston, K.C.B.; being a fifth contribution to the Mammalogy of Nyasaland." This memoir contained notes on sixty-one species of Mammals, four of which were characterised as new, viz. *Macroscelides brachyrhynchus malosæ*, *Crocidura lixa*, *Myosorex soulla*, and *Graphiurus johnstoni*.—A communication was read from the Rev. O. Pickard Cambridge, F.R.S., describing a new genus and species of Acaridea (*Eatonia scopulifera*) from Algeria.—A communication by Mr. J. Stanley Gardiner, "On some collections of corals of the family *Pocilloporidæ* from the South-west Pacific Ocean," was read by the author. Twenty species of the genus *Pocillopora* and one of the genus *Seriatopora* were enumerated and remarked upon, five species of the former genus being described as new, viz. *Pocillopora septata*, *P. obtusata*, *P. coronata*, *P. rugosa*, and *P. glomerata*.—Mr. W. E. de Winton gave an account of a collection of Mammals from Morocco, made by Mr. E. Dodson on behalf of Mr. J. I. S. Whitaker. Twenty-one species were enumerated as represented in the collection, of which the following were described as new: *Crocidura whitakeri*, *Mus peregrinus*, and *Lepus atlanticus*.

DUBLIN.

Royal Dublin Society, November 17.—Dr. F. T. Trouton, F.R.S., in the chair.—Dr. G. Johnstone Stoney, F.R.S., presented a paper upon atmospheres upon planets and satellites (see p. 207).—Mr. W. E. Wilson, F.R.S., read a paper upon the apparent cometary nature of the spiral nebula in Canes Venatici. The paper was illustrated by a remarkably fine photograph of the nebula taken in February 1897, by the author.—Dr. F. T. Trouton read a paper upon the arrangement of the crystals of certain substances on solidification.—Prof. A. C. Haddon presented a paper upon the Actiniaria of Torres Straits. This account of the Actiniaria is based mainly on the collections made by the author in 1888–9, supplemented by descriptions published by Mr. Saville-Kent in his works "The Great Barrier Reef of Australia" and "The Naturalist in Australia." In order to render the paper more complete, allusions are made in it to genera which are not recorded from Torres Straits. In a second paper, Prof. Haddon described a new species of Actiniaria from Oceania—*Phellia Sollasi* This was collected by Prof. Sollas in the lagoon at Funafuti, Ellice Group, W. Pacific, in 1896.—The following objects were exhibited at this meeting: The Coccoliths of Dublin Bay, by Mr. H. H. Dixon, and Prof. J. Joly, F.R.S.—A collection of economic plant products from the Gold Coast, by Prof. T. Johnson.

ST. LOUIS.

Academy of Science, December 6.—Mr. Julius Hurter exhibited specimens of a considerable number of reptiles and batrachians, mostly of southern origin, which had been collected by him during the past season, and were additions to the known fauna of Missouri. Among the more interesting additions were the cotton-mouth moccasin, the banded water snake, Holbrook's water snake, the little brown snake, the Louisiana mud turtle, the chestnut-backed salamander (first detected west of the Mississippi River by Mr. Colton Russell), and the marbled salamander.—Mr. H. von Schrenk exhibited a series of specimens and drawings illustrating some of the injuries inflicted on the trees of St. Louis by the tornado of May 1896, showing not only the formation of double twig elongation and growth rings, but the exfoliation of the bark and the consequent drying out of 50 per cent. or more of the wood through the trunk and branches, in several species.

NEW SOUTH WALES.

Linnean Society, October 27.—Prof. J. T. Wilson, President, in the chair.—Descriptions of new species of Australian Coleoptera, Part 4, by Arthur M. Lea. Thirty-four species, principally belonging to the *Curculionidæ*, were described as new; with critical notes and remarks on synonymy.—On the lizards of the Chillagoe district, North Queensland, by Dr. R. Broom. Twenty-three species were collected during a six months' residence at Muldiva, seventy miles west of Herberton, a district in which during eight months of the year (April–December) as a rule there is practically no rain. A species of *Lygosoma* was described as new.—On a *Trachypterus* from New South Wales, by J. Douglas Ogilby. In this paper the author gave a detailed description of a young example washed ashore near Newcastle, and reviewed at length our present knowledge of the genus in the south-western Pacific.—Contributions to a more exact knowledge of the geographical distribution of Australian Batrachia, No. 5, by J. J. Fletcher. The present contribution is based upon the examination of collections from Tasmania and West Australia. In the British Museum Catalogue (second edition) seven (? eight) species are attributed to Tasmania, and fourteen to West Australia. Three additional species are now recorded for the former Colony, and six for the latter, including an undescribed species of *Crinia* belonging to the group having the abdominal surface non-granulate.—Mr. Froggatt exhibited a number of scale insects (*Eriococcus coriaceus*, Mask.), upon a twig of Eucalyptus, among which had been placed a great number of the eggs of the scale eating moth *Thalpochares coccophaga*, Meyr. The eggs are pale pink, circular, and beautifully ribbed. The scales were infested with the larvæ of *Cryptolæmus montrouzieri*, Muls., a useful small black ladybird beetle. Both these enemies of *Eriococcus* are of great economic value, as the moth larvæ have now taken to eating the olive scale (*Lecanium oleæ*, Sign.), and the ladybird beetle is bred both in New Zealand and America. Also living specimens of our largest white ant, *Calotermes longiceps*, Froggatt, which were taken out of a log of fire-wood, and had already been in captivity for over two months.

DIARY OF SOCIETIES.

MONDAY, JANUARY 3.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—Standard Methods of Tanning Analysis as adopted by the International Association of Leather Trades Chemists, with Remarks thereon: Prof. H. R. Procter and Dr. J. G. Parker.—Extraction of Tanning Materials at various Temperatures: Dr. J. G. Parker.—Neatsfoot Oil: J. H. Coste and E. J. Parry.

VICTORIA INSTITUTE, at 4.30.—Ancient Civilizations: Rev. John Tuckwell.

TUESDAY, JANUARY 4.

ROYAL INSTITUTION, at 3.—The Principles of the Electric Telegraph: Prof. Oliver Lodge, F.R.S.

ROYAL VICTORIA HALL, at 8.30.—Coal: W. F. Rudler.

WEDNESDAY, JANUARY 5.

GEOLOGICAL SOCIETY, at 8.—On the Structure of the Davos Valley: A. Vaughan Jennings.—Sections along the Lancashire, Derbyshire, and East Coast Railway, between Lincoln and Chesterfield: C. Fox-Strangways.

THURSDAY, JANUARY 6.

ROYAL INSTITUTION, at 3.—The Principles of the Electric Telegraph: Prof. Oliver Lodge, F.R.S.

FRIDAY, JANUARY 7.

GEOLOGISTS' ASSOCIATION, at 8.—A Brief Account of the Excursions in the Urals, down the Volga, in the Caucasus, &c, made in connection with the Interntional Geological Congress held in Russia, August–September, 1897: L. L. Belinfante.

SATURDAY, JANUARY 8.

ROYAL INSTITUTION, at 3.—The Principles of the Electric Telegraph: Prof. Oliver Lodge, F.R.S.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—L'Electro-chimie: A. Minet (Paris, Gauthier-Villars).—Introduction to the Study of Organic Chemistry: J. Wade (Sonnenschein).—Natürliche Schöpfungs-Geschichte: Prof. E. Haeckel, 2 Vols., Neunte Umgearbeitete Auflage (Berlin, Reimer).—Notes on Carpentry and Joinery: T. J. Evans, Vol. 1 (Chapman).—What is Life?: F. Hovenden (Chapman).—The Collected Mathematical Papers of Arthur Cayley, Vol. xiii. (Cambridge University Press).—Physikalisch-Chemische Propaedeutik: Prof. H. Griesbach, Zweite Hälfte, 2 Liefg (Leipzig, Engelmann).

PAMPHLETS.—Magnetic and Pendulum Observations: G. R. Putnam (Boston, Mass.).—Hand-Guide to the Botanic Gardens, Buitenzorg (Batavia, Kolff).

SERIALS.—Traité Encyclopédique de Photographie: Dr. C. Fabre, Cinq^e Fasc. B. (Paris, Gauthier-Villars).—Journal of the Royal Microscopical Society, December (Williams).—Century Magazine, January (Macmillan).—Quarterly Journal of Microscopical Science, December (Churchill).—Natural Science, January (Dent).

CAYLEY'S PAPERS.

The Collected Mathematical Papers of Arthur Cayley, Sc.D., F.R.S. Vols. viii., ix. Pp. liv + 570, xvi + 622. (Cambridge: at the University Press, 1895, 1896.)

THESE two volumes form the first of those published after Cayley's death in 1895. The first thirty-eight sheets of Vol. viii. were revised by the author, who added a note on one paper (No. 518); the duty of editing the rest of the papers was entrusted to Prof. Forsyth, who has very faithfully carried out the plan and arrangements which, in the absence of definite instructions, he was able to infer from the previous volumes.

Perhaps the reader's first impression after surveying these 144 papers, mostly published in the years 1871–77, is that they are very miscellaneous, and that comparatively few are of paramount importance. The fact is that Cayley is, as it were, brought into unfavourable comparison with himself; short notes on special problems of geometry and analysis, and solutions of Smith's Prize papers cannot rank with the immortal "Memoirs on Quantics," or some of the earlier geometrical papers, such as that upon plane cubic curves. But it is unreasonable to expect an artist to produce an uninterrupted succession of masterpieces; and it is to be remembered that Cayley seldom, if ever, wrote upon any subject without developing some instructive point or giving an example of his own characteristic elegance.

In trying to give some account of the more important of these memoirs it will be convenient to take the geometry and the analysis separately. Not that the boundary line is very easy to fix: Cayley was never a geometrician in the sense in which the word may be applied to Apollonius or Steiner. But some of the papers have an interest mainly geometrical, although the methods used are almost wholly algebraic; and with them we will begin.

Perhaps the most important are those which deal with transformation, correspondence, and the singularities of algebraical curves and surfaces. With these difficult theories Cayley dealt in a masterly way: he avoided, as if by instinct, the many opportunities of mistake which present themselves in a method which is largely enumerative, and he had the gift of predicting general results from the consideration of special cases.

Coming next to what may be called the metrical geometry of surfaces, which has developed so greatly in recent years, we have papers on curves of curvature, on geodesics on quadrics, and on orthogonal surfaces. To this group may perhaps be added a paper on evolutes and parallel curves, though this is rather meant to illustrate the non-Euclidian geometry.

There are three monographs, on Steiner's surface, on the centro-surface of an ellipsoid, and on the configuration of the twenty-seven lines of a cubic surface, which are in various ways highly characteristic. As models of analytical skill they are admirable; and as helps to the understanding of the geometrical figures with which they deal, they are of great service. But it is curious to see how chary the author is in giving illustrative diagrams. There are, indeed, two figures in the paper on the surface of centres; but why, we ask, did Cayley not give a series of contour lines of the surface? or again, with still more reason, in the case of Steiner's surface? Then the paper on the twenty-seven lines of a cubic surface is so quaint in its topsy-turveydom as almost to suggest Mr. W. S. Gilbert as joint author. Here we have a projective configuration which may be realised with the help of a bundle of sticks and without any measurement whatever. What Cayley did was to take a model by Dr. Wiener, measure approximately the coordinates of a number of points upon it, thence find the approximate equations of the lines, and finally adjust the equations so as to satisfy the geometrical conditions! Of course there is reason in this seeming perversity: by the projective method it is not easy to get a convenient arrangement of the sticks, whereas Cayley's equations make it possible to construct a string model on a cardboard frame without a tiresome series of preliminary experiments.

The poristic polygons of Poncelet appear to have had for Cayley a perennial charm: we have here two papers suggested by Poncelet's results; one "On the porism of the in-and-circumscribed polygon, &c.," which treats of the original problem, and the other "On the problem of the in-and-circumscribed triangle," which really deals with a rather different and more general theory. Cayley, like many others, does not seem to have been aware (at least in 1871) that the complete algebraical solution of the Poncelet problem was published in 1863 in a paper by M. Moutard, which formed part of the appendix to Poncelet's "Applications d'Analyse à la Géométrie." Not only is this so, but, as Halphen pointed out, this paper contains the first fully satisfactory treatment of the multiplication of the argument in elliptic functions.

Before passing on from the geometrical papers, attention should be called to the very interesting series of notes on the mechanical description of curves. This is a promising field of research, and the results could hardly fail to be of interest, especially to those who like to see the deductions of theory embodied in an actual geometrical figure. There is an æsthetic satisfaction in this contemplation: and, moreover, a really correct figure often suggests geometrical truths that would otherwise be overlooked.

Of the analytical papers the one which has been most appreciated in this country is, beyond question, the short paper "On the theory of the singular solutions of differential equations of the first order" (*Messenger*, vol. ii. (1873) pp. 6–12). Here Cayley's power of giving to analysis a geometrical interpretation appears to the best advantage. If we have an algebraical relation $f(x, y, p) = 0$ in which p enters to the degree s, then this associates with any point (x, y) a series of s (real or imaginary) directions corresponding to the different values of p: in other words, the differential equation really expresses that the plane of reference is covered with ∞^2 tiny s-rayed stars. The primitive $\phi(x, y, c) = 0$ gives a family of ∞^1 curves each made up of ∞^1 selected rays. Now if we eliminate p from $f(x, y, p) = 0$, $\partial f / \partial p = 0$, we obtain a locus of points (x, y) at each of which two rays coincide in direction; where this happens either two consecutive curves $\phi(x, y, c) = 0$ touch, or two non-consecutive curves touch, or (x, y) is a cusp or point of self-contact of one particular curve $\phi(x, y, c) = 0$. Thus we may have the envelope of the family of curves, a tac-locus, or a locus of cusps or of points of self-contact. On the other hand if we eliminate c from $\phi(x, y, c) = 0$ and $\partial\phi/\partial c = 0$, we get the locus of intersection of consecutive curves ϕ: this may include besides the envelope proper, a locus of nodes, of cusps, or of multiple points of higher order (as, for instance, points of self-contact or triple points). The only outstanding difficulty is the degree of multiplicity in which the singular loci, distinct from the envelope, are involved in the two discriminants.

There are six papers on the transformation of elliptic functions, the most important being No. 578. This contains an exposition of the Jacobian theory, Sohnke's modular equations with additions, and a discussion of the singularities of some of the modular curves. It is remarkable that Cayley, like Kronecker, adhered firmly to Jacobian methods, and never seems to have worked with the Weierstrassian forms. Perhaps just now there is a rather exaggerated tendency in the other direction: as Prof. Klein has pointed out, both theories are self-consistent and form, in a sense, the first and second stages in a complete discussion of periodic functions.

There is not very much about invariants and covariants; No. 525 is an interesting example of a quadratic transformation, and the papers on "trees," although ostensibly intended for application to chemistry, were suggested by the invariant calculus.

In arithmetic there is a table of reduced binary cubics with their Hessians, which is a development of Arndt's results. Cayley gives the composition tables for the Hessians.

Volume ix. contains eleven papers dealing more or less with astronomy and dynamics; and it may be worth while to notice that this volume also contains a reprint of the British Association "Report on Mathematical Tables."

Many interesting special points suggest themselves to the reader: thus, to mention only three, very different in character, the very simple and pretty proof of Vandermonde's theorem (viii. p. 465) might very well find a place in an elementary text-book of algebra; we are told (*ibid.*, p. 188) how a theoretical error was detected by a numerical calculation; and (*ibid.*, p. 397) there is an unverified conjecture that every surface of negative deficiency may be derived by a rational transformation from a cone whose deficiency is equal to that of the surface with its sign changed.

G. B. M.

EXPERIMENTAL PHYSICS.

The Outlines of Physics. By Prof. E. L. Nichols. Pp. xi + 452. (London: Macmillan and Co., Ltd., 1897.)

Lessons in Elementary Practical Physics. Vol. iii. Part i. *Practical Acoustics.* By C. L. Barnes. Pp. x + 214. (London: Macmillan and Co., Ltd., 1897.)

THE first of these books, as the author explains in his preface, is an attempt to "outline a short course in physics which shall be a fair equivalent for the year of advanced mathematics now required for entrance to many colleges"; and he proceeds to point out that if physics is to possess much disciplinary value, it must be taught by laboratory methods. Experimental work thus finds a prominent place in his book, which may, in fact, be roughly described as a series of experiments, mostly suitable for repetition by young students, connected by short discussions of a theoretical character.

With the author's object we imagine that most teachers of physics will cordially sympathise. That experiment is the means whereby a knowledge of physics should be acquired by beginners, is as clear now-a-days as it is that the means itself is open to improvement—at any rate, in its early stages. Whether the author has made the most of his opportunity is, however, less certain. Much of his work is excellent: the experiments are, for the most part, well chosen and clearly described; but after a careful perusal of his book, one's prevailing impression is that he has attempted to include too much.

A book of this kind is, of course, largely taken up with description of experimental procedure; but the space is often further occupied with matter which might, in our opinion, be left until a later stage in the student's career. Such questions as X-rays, tests for and theory of colour-blindness, interference and polarisation of light, are too large for more than the briefest notice, and might therefore just as well have been omitted altogether; especially when, to mention one instance out of many, curved mirrors are dismissed with a far too scanty discussion, and no special experimental illustrations at all. It would, in our opinion, have been better to develop further the experimental treatment of the simpler parts of physics at the expense of these more elaborate phenomena. It is only in places, however, that the work is affected by this fault; and the same may be said of an occasional laxness of expression which will probably lead to mistakes on the part of young readers where it occurs. Taken as a whole, the book forms a useful addition to the elementary text-books on practical physics.

We have noticed a few points that rather need alteration. In the figure of the apparatus for determining the heat of vapourisation of water (p. 172), the long tube connecting flask and calorimeter should be provided with a trap for the steam condensed in it. The statement in italics on p. 213, that "various bodies can be brought by friction (*i.e.* by doing work upon them) into a condition such that they attract and are attracted," is rather misleading. It is, of course, the work done in pulling the rubber and rubbed object apart which should be emphasised. On p. 337, in the figure illustrating the motions of the air in sound waves, the arrows want altering; on pp. 308 and 310, misprints of iron for ion, and ammonium for ammonia, respectively, occur; and on p. 99, in the last column the decimal point has gone astray.

The general get-up of the book is, as one would expect, excellent; and the diagrams, which are mostly by Mrs. Nichols, are very clear and well executed. We may add that the work is almost wholly non-mathematical.

The second of the two books named at the head of this notice, forms the first part of vol. iii. of the "Elementary Practical Physics" series begun in 1885 by Prof. Balfour Stewart and Mr. W. W. Haldane Gee.

With the rapid development of the teaching of physics by laboratory methods, now in progress, has arisen the growing need of a good practical and elementary course on sound. The present work admirably supplies this need, and constitutes a worthy companion to the well-known volumes already published in the Stewart and Gee series. The author is, moreover, thoroughly familiar with the experimental side of his subject; besides being clearly and concisely written, his work is thus rendered very interesting to read.

Starting with chapters on the nature of sound and wave motion, he discusses in the following order the sonometer, resonance, determination of frequency, rods and plates, tuning forks, pipes, harmonic motion, reflection and refraction of sound, velocity of sound, Döppler's principle, musical scale, analysis of sounds, interference, beats, differential and summational tones, &c. The book ends with a useful list of workers in theoretical and experimental acoustics, with dates of birth and death.

Sound is a subject which lends itself to pretty experiments, and there is no lack of such here. To choose one instance out of many, we may refer to Expt. xc., in which the refraction of air waves in the Sondhauss experiment is imitated in water by making ripples pass over a shallow circular patch in a deeper sheet of water, and thus retarding them as the air-waves are retarded by the CO_2.

More might perhaps be made of the india-rubber cord as an illustration of the properties of stretched strings. By causing a metronome to beat at the same rate as a horizontally stretched cord, it is easy to obtain good quantitative results, while the slowness of the vibrations is a great help to unimaginative students in subsequently understanding the behaviour of stretched wires.

There is a mistake in the diagram on p. 22, where, of the two quantities plotted, one should be replaced by its reciprocal if the result is to be a straight line. On p. 105 there is a 2 omitted from the equation for t.

These are, however, trifling slips in a work for which teachers of physics cannot fail to be grateful to the author.

A. P. C.

AMERICAN GAME BIRDS.

The Gallinaceous Game Birds of North America. By D. G. Elliot. 8vo, pp. xviii + 220, illustrated. (London: Suckling and Co., 1897.)

THE author of this little volume is already so well known to naturalists from his splendid illustrated folio monographs of various groups of mammals and birds, that any work from his pen needs but little in the way of commendation. Among his monographs are two respectively devoted to the grouse and pheasants, and it is the American representatives of these groups that he now describes in a less elaborate form, and with the advantage of all the observations recorded since the publication of his larger works. The present volume is indeed the companion to the author's "North American Shore Birds," which has already been well received; and since a large number of British sportsmen now visit the States, the demand for the work ought to be considerable. Although not so good as some we have seen, the photogravures with which the work is illustrated are for the most part of a fair grade of excellence, and afford every facility for the identification of any specimen with which the naturalist or sportsman may meet.

The work commences with a general dissertation on game birds and their affinities, written in such a popular, and at the same time such exact, style, that it should prove acceptable to readers of every class. Following this is a description of the habits and characteristics of the various North American representatives of the group, which, inclusive of subspecies, total up to forty-four. A feature of the work is that the main portion of the text devoted to each form is headed solely by the popular name of the particular species or race; the technical name and detailed description coming at the end of each section. In view of the general shuffling of scientific names now taking place in all classes of animals, their relegation to a subordinate position in a popular work is by no means inadvisable; and those readers who so desire, can easily skip the technical portions altogether.

Apart from these technical descriptions, the work is written in a bright and attractive manner, the habits of the different species being noted in considerable detail, and their geographical distribution most carefully worked out. It will be a matter of satisfaction to many to learn that while certain kinds of game birds are dying out from the effects of persecution in the more settled districts, some others are gradually making their way to the wilder districts of the west, where they will meet with better chances of survival.

As many of our readers are aware, with the exception of the grouse and ptarmigan, which have a circumpolar distribution, the game birds of North America are totally distinct from those of the Old World; the pheasants, quails, and partridges of the latter being quite unknown in the former area, where their place is taken by the so-called American partridges. The author might have explained that this difference is doubtless due to the inability of either of these groups to withstand the cold of high northern latitudes which apparently prevailed at the time of a land bridge *viâ* Bering Strait. A parallel instance is afforded by the absence of hyænas and civets from America.

As regards classification, the author departs considerably from the view usually adopted in Europe. Instead of restricting the *Tetraonidæ* to the grouse and ptarmigan, he includes in that family the Old World *Perdicinæ* and the American *Odontophorinæ*, both of which are usually placed in the *Phasianidæ*. Apart from all other considerations, the circumpolar distribution of the grouse and ptarmigan renders it in the highest degree desirable that they should be kept as the sole representatives of a family differing by its distribution from all the other groups of the order.

A series of coloured papers illustrating the colour-terms employed in the text concludes this well-written and useful compendium of North American game birds.

R. L.

OUR BOOK SHELF.

L'Éclairage à l'Acétylène. Par G. Pellissier. Pp. 237. (Paris: Carré et Naud, 1897.)

IN England the discovery of calcic carbide, and the ease with which acetylene may be prepared from it, has attracted a large amount of attention; but the literature of the subject is practically restricted to a few papers read before various societies and to the returns of the

Patent Office, whereas in France the subject has been considered of sufficient importance to justify the compilation of several fairly bulky works.

Well illustrated and clearly written, M. Pellissier's volume on "L'Éclairage à l'Acétylène" will be found both useful and interesting to the large number of persons who are now taking a lively interest in the future of this new illuminant.

The work opens with a chapter on the physical and chemical properties of acetylene, and a description of the methods by which it has been made since its discovery by Edmund Davy in 1836, a valuable portion of the chapter being devoted to the dangers attributed to its use under low pressures, a consideration of which leads to the conclusion that under these conditions it is no more dangerous than coal-gas.

The question of electric furnaces is then discussed, and illustrations of the forms in use and proposed are given; and this is naturally followed by a chapter on the carbide itself and the various data obtainable as to its cost, the results obtained by the Committee of Investigation appointed by the editor of the *Progressive Age* in America being largely quoted. Such discussions, however, are of but little use, as the cost of the carbide must vary largely with the cost of the power needed to generate the electricity and the facilities for cheap carriage.

It may be taken as proved that under the conditions at present existing the carbide cannot be made at less than from 7*l.* to 10*l.* per ton in France or in England; whilst the selling price is entirely in the hands of the manufacturer, and amounts to from 16*l* to 20*l.* per ton. In treating of the methods by which acetylene can be generated from the carbide and the generators used or suggested for that purpose, the author very conveniently divides the generators into three classes: those in which acetylene is generated by allowing water to drip on carbide, those in which water is brought in contact with carbide by change of level, and finally, those in which the carbide is dropped into water.

There is not the least doubt that the last is by far the best method to employ, as the gas evolved is far purer, and dangerous rise of temperature is avoided.

The question of portable lamps, acetylene in a liquefied and compressed condition, and its solution in acetone are all dealt with, and no attempt is made to gloss over the dangers incurred directly ordinary pressures are far exceeded. The last three chapters of this little work are devoted to the subject of the conditions existing in the acetylene flame, the forms of burners for its consumption, the relative price of acetylène as an illuminant, and practical directions for its use.

The weakest part of this capital work is that in which the author, with true patriotism, attempts to prove the priority of M. Moissan in discovering the possibility of manufacturing calcic carbide in the electric furnace; whilst facts show that the Canadian, Willson, had made crystalline calcic carbide in the electric furnace, and had privately sent specimens of it to scientific friends, several months before Moissan first mentioned its accidental formation.

Atlas der Himmelskunde auf Grundlage der Ergebnisse der coelestischen Photographie. By A. v. Schweiger-Lerchenfeld. (Vienna: A. Hartleben, 1897.)

HERR VON SCHWEIGER-LERCHENFELD set himself no light task when he undertook the work of selecting and publishing the material gathered together in this beautiful atlas. A glance through the first few parts shows that no pains have been spared, either in the selection and reproduction of the photographs or in the text, to make the volume, when completed, of most absorbing interest to any one who wishes to know something outside this little earth of ours.

The aim of the compiler has been to fully illustrate by the best processes available, and to explain by accompanying appropriate text, the wonders of the universe as they have been revealed to us by means of that most valuable aid to science—photography. Herr v. Lerchenfeld has been fortunate enough, not only in obtaintaining the aid of most of the chief astronomers connected with observatories in which photography is employed, but in receiving valuable information from the most skilled instrument-makers of to-day. The result is that the atlas is full of beautiful reproductions of many of the finest photographs ever taken of celestial bodies, and the instrumental equipment of modern observatories is fully included.

It would be impossible to enumerate the many and various subjects which are here dealt with, so it must suffice to give a brief summary of the more prominent features. It may, however, be first remarked that the atlas in a completed state will contain over 50 large plates and about 135 single reproductions, the text being accompanied by no less than 500 additional illustrations. Nearly one third of the latter is devoted to a description of the various astronomical instruments now at work in the chief observatories of the world. This section is of great interest, and will be found useful, as a great amount of information is here brought together. The fine reproductions of the best lunar landscapes will be found invaluable to selenographers, as particular care has been bestowed on these to render them accurate. Stellar photography is richly and beautifully illustrated, and one really revels among the best illustrations that have yet been brought together in one volume. The plates illustrate the results of employing lenses varying from one to thirty-six inches, with periods of exposures varying from minutes to several hours.

Cometary, solar, spectroscopic and planetary photography all fall within the compiler's reach, so that a reader's desire for a good astronomical picture book is here fully satisfied.

In conclusion we may say that this atlas is well worth obtaining, if only for the illustrations themselves, and it will be found serviceable not only in observatories, but in schools and teaching centres. W. J. S. L.

Knowledge. Vol. xx. January to December 1897. Pp. xii + 304. (London: *Knowledge* Office.)

THIS well-known popular magazine of science is as good to-day as ever it was. The illustrations, especially the full-page plates, are excellent, and the articles cover a variety of scientific subjects. Special characteristics of the volume are a series of articles on the science of the Queen's Reign, and the prominence given to ornithological notes.

LETTERS TO THE EDITOR

Physiology and the Royal Institution.

ALL interested in physiology must notice with regret the retirement of the late Fullerian Professor of Physiology from his appointment at the Royal Institution, after expiration of only one year's tenure. His resignation leaves a valuable and notable course of lectures incomplete, to the disappointment of many whom they keenly interested. His withdrawal removes in mid-career a teacher of recognised ability from a chair to which he was devoting himself with conspicuous success. Matter for regret this it seems cannot, however, be taken as matter for surprise, if I judge rightly in connecting with his resignation a letter appearing last July in your columns; there the Fullerian Professor pointed out that the practical circumstances attaching to the chair almost preclude possibility to treat its subject as a province of experimental science. Physiology, inseparable from chemistry and physics, could, one might have imagined, at an Institution so famous for the character of its lectures on those subjects, have been advantageously placed. That, from Prof. Waller's letter, is evidently the reverse of its present case at the Royal Institution. Not a workroom, even of the smallest size, could he obtain for conduction or preparation of his experiments. This must be a revelation to many who know the Institution as connected with the names of men, such as Davy and Faraday, who contributed by research to physiology—who, in other words, considered the chemistry and physics of living material as well as that of dead to lie within the scope of study and inquiry supported by the Institution. It is true that the Fullerian chair of Chemistry has proved fruitful in measure exceeding the productiveness of the Fullerian chair of Physiology. The latter has been declared comparatively *sterile*. *This is regrettable; but its reason does not seem far to seek.* Both chairs have been held by men of high distinction; but the former has rested upon a laboratory, while the latter—so far from resting upon a laboratory—"does not possess even one small room in which to keep itself alive." Is this condition irremediable? I ask although by circumstance outside the Institution; and ask simply as one interested in the welfare of physiological science, and as a unit of a public who esteem the Institution as a place of instruction for the educated masses of a great city where at present such opportunities as the Institution offers are lamentably few.

Liverpool, December 31, 1897. CH. S. SHERRINGTON.

A Mechanical Theory of the Divining Rod.

THE review in NATURE (October 14, 1897, pp. 568, 569) of a publication relating to the "divining rod," recalls to my mind a purely mechanical theory of that rod, which was given me years ago by a friend.

This theory has been repeatedly tested by me and shown to be correct in the presence of my classes. The process is exceedingly simple. Take any forked twig of a reasonably tough fibre in the clenched hands with the palms upward. The ends of the limbs forming the twig fork should enter the closed fists *on the exterior side of each fist, i.e. on the two sides of the* clenched hands furthest from each other.

When a twig is grasped in this position it will remain stationary if held loosely, or with only a moderately firm grasp; but the moment the grasp is tightened, the pressure on the branches will force the end of the twig to bend downwards. The harder the grip the more it must curve.

The curvature of the twig is mechanically caused by the pressure of the hands forcing the limbs to assume a bent and twisted position; or the force that causes the forked limb to turn downwards is furnished by muscles of the hands, and not from any other cause.

The whole secret of the "divining rod" seems to reside in its position in the hands of the operator, and in his voluntarily or involuntarily increasing the closeness of his grasp on the two ends of the branches forming the fork.

If the above conditions are fulfilled the twig will always bend downwards—water or no water, mineral or no mineral; any one can be an operator, and any material can be used for the instrument, provided the limbs forming the fork are sufficiently tough and flexible.

It can be easily understood how an ignorant operator may deceive himself, and be perfectly honest in supposing that some occult force, and not his hands, causes the fork to curve downwards. M. E. WADSWORTH.

Growth of the Tubercle Bacillus at a Low Temperature.

A BROTH culture of the tubercle bacillus a month old was filtered through a sterilised Berkfeld filter; the filtrate was ascertained to be sterile; it was then sown with a trace of *B. tuberculosis* and incubated at a temperature varying slightly between 18°–20° C., but never higher than 20°.

The bacillus developed well, but not so rapidly as at the customary temperature, *i.e.* 37·8° C.; the growth had not the usual flocculent appearance, but was granular.

Microscopically the organism was unchanged.

London, December 20, 1897. F. J. REID.

THE STORY OF GLOUCESTER.

1979 cases of small-pox, 434 deaths; or a mortality of 21·9 per cent. during a period of thirteen months.

	Cases.	Deaths.	Percentage mortality.
Previously vaccinated ...	1211	120	9·8
Unvaccinated	768	314	40·8
	1979	434	

SUCH, in brief, is the story told by Dr. Sidney Coupland in his Report to the Royal Commission on Vaccination on the outbreak of small-pox in the city of Gloucester in 1895-96.

These figures, in all their baldness, convey a lesson such as no long garnished account can accentuate or emphasise; but in Dr. Coupland's Report a number of most interesting facts and statistics have been brought together, which will form the basis of many future reports and arguments.

One of the most interesting points brought out, apart from the mortality, was the proportion of severe and mild cases in vaccinated and unvaccinated patients. Of those vaccinated in infancy, there suffered from—

	Per cent.	
Malignant small pox	2·4	of the whole of those attacked.
Confluent ,,	19·1	,, ,,
Coherent ,,	9·6	,, ,,
Discrete ,,	28·7	,, ,,
Mild ,,	40·0	,, ,,

When we come to those who are said to have been vaccinated, but of which there is no very strong evidence, we find:—

	Per cent.	
Malignant small-pox	17·5	of the whole of those attacked.
Confluent ,,	52·5	,, ,,
Coherent ,,	10·0	,, ,,
Discrete ,,	12·5	,, ,,
Mild ,,	7·5	,, ,,

Being a marked rise in malignant and a great fall in mild cases.

Amongst the unvaccinated the proportion of severity of attacks at all ages was:—

	Per cent.
Malignant small-pox	5·0
Confluent ,, ...	72·3
Coherent ,, ...	10·3
Discrete ,, ...	8·7
Mild ,, ...	3·6

Showing a very high percentage, indeed, of the severe type of case.

These figures are given in full because they afford evidence, quite apart from the mortality, of the enormous influence that vaccination exerts on the course of an attack of small-pox.

The Gloucester epidemic appears to have differed from almost every other recent outbreak of small-pox in the fact that its incidence was especially heavy on infants and young children. Below one year the proportion of deaths was no fewer than 14 per cent. of the whole, whilst at ages from 1 to 10 years it was exceedingly heavy—50·4 per cent. This, of course, was accompanied by a corresponding diminution in the proportion of deaths at later years; and from 10 to 30 years the proportion had fallen to 12·6 per cent., though from 30 years and upwards (the effect of early vaccination having worn off to some extent) it had again risen to 22·7. When these figures are compared with the earlier outbreak of 1873-75 in Gloucester and with the Dewsbury and Leicester outbreaks, it is found that the proportion of deaths amongst children is exceptionally high. It was noticed, too, that the disease spread amongst these children with enormous rapidity, and that it occurred amongst them in an exceptionally severe type, both as regards the proportion of malignant cases and the height of the mortality.

It is certainly not going beyond the facts of the case to state that the above-mentioned characteristics of this epidemic must in great measure be attributed to the large number of unvaccinated children who were in attendance at school, and who were thus not only extremely susceptible to the attacks of small-pox, but were in a position to disseminate the disease, though in a milder form, amongst those who had been vaccinated. That is, the neglect to have the children vaccinated left them in a condition in which they would readily take small-pox just at the time when their surroundings were of such a nature that everything was favourable to their taking the disease from one another, and in turn passing it on to those with whom they daily came in contact; with the result, as Dr. Coupland points out, that one in twenty of the whole population of Gloucester were struck down with small-pox. Indeed, he goes so far as to say that, "viewing the subject with as impartial a mind as I can, the conviction is forced upon me that Gloucester would not have suffered as it did had its child population been vaccinated." It was this want of vaccination, and the impossibility of maintaining effective isolation of the attacked, that allowed of the abnormally rapid spread of the disease after it has once obtained a firm hold in the city.
